If all the other modes have zero amplitude, the ions move radially towards or away from the central luminescent ion. The key point in considering the influence of the crystal lattice is that the vibrational potential energy is just the variation of the electronic energy with ionic displacement, or equivalently with the normal modes (within the spirit of the Born–Oppenheimer approximation). Put another way, the crystal field depends on the ion positions so that the electron and lattice quantum-mechanical systems are linked through this electron–lattice coupling. We can therefore expect a difference in the harmonic vibrational potential from one electronic state to another, so that it will in general have the form $(1/2)m\omega_i^2(Q - Q_{0i})^2$; i.e. both the magnitude of the potential and the position of the minima Q_{0i} will depend on the electronic state i . The vibrational states in the harmonic approximation are just the usual simple harmonic oscillator states with energies $(n + 1/2)h\nu_i$,

Fig. 40.3 Configuration coordinate diagram for excitation/emission cycle

with n an integer. Thus we arrive at a *configuration coordinate* diagram such as that shown in Fig. 40.3, with the potential energies for a ground state g and excited state e being offset parabolas of different curvature. The square of the vibrational wavefunction is shown for the ground state and that with $n = 11$. We note that for a classical oscillator there would be a peak in the probability function at the extreme lengths of travel, corresponding to the maxima for $n = 11$ at the outer limits of the wavefunction in Fig. 40.3.

We consider first luminescence from the excited electronic state/lowest vibrational state. The transition probability may be calculated using the Franck–Condon principle, that is we assume that the duration of the electronic transition is much shorter than a vibrational period, so that the Q remains constant during a transition. The transition is therefore taken to be *vertical* on the configuration coordinate diagram. The transition probability is just $\langle \phi_e | \phi_g \rangle^2$, the square of the vibrational wavefunction overlap, multiplied by the electronic transition probability considered earlier. From Fig. 40.3, this overlap will be a maximum for some vibrational state other than the ground state, unless the positions of the minima of the two potential energy curves coincide accidentally. (In Fig. 40.3, this maximum would be for the $n = 11$ ground vibrational state). Put another way, the maximum transition probability is not

Fig. 40.4 Absorption and emission line shapes for strong electron–lattice coupling

for the zero-phonon transition (no change in vibrational state), but corresponds to the creation of a finite number of phonons. A range of transitions is allowed, and the result in a semiclassical analysis, allowing for finite line widths, is a Gaussian-shaped band. The analysis has to be extended to include finite temperatures and other modes, but the overall result is that the emission line shape is approximately a Gaussian centred at an energy lower than that of the difference between the minima of the two potential curves. The same argument can be applied to the excitation process, and again an approximately Gaussian line shape results but this time centred on an energy above that of the difference in potential-energy minima. Figure 40.4 shows the overall result; the difference between the maxima of the two curves, known as the Stokes shift, is an indicator of the degree of electron–lattice coupling.

It is clear from the diagram that the, in cases where there is strong electron–lattice coupling of this type, that: (a) there will be very little intensity in the zero-phonon line, and (b) there will be a large Stokes shift between the energies for maximum absorption and maximum emission. Thus the luminescence of transition-metal ions, colour centres, and closed-shell ground-state ions (s^2 , d^0), which have strong interactions with the lattice in the excited states, are typically broad bands with only occasionally weak, sharp zero-phonon lines being observed. For luminescence from within the 4f states of the rare earths, the reverse is true; we are in the weak-coupling regime, and zero-phonon lines are the predominant features of the spectrum.

40.3 Thermally Stimulated Luminescence

Thermally stimulated luminescence (TSL), or simply thermoluminescence (TL), refers to luminescence induced by thermally stimulated recombination of trapped electrons and holes in materials which have been subject to prior irradiation. The irradiation, which may be in the form of UV light, X-rays, gamma rays, or energetic electrons, creates free electrons and holes, most of which promptly recombine, but some of which are locally trapped at defect centres such as impurities and vacancies. If the trap binding energies are sufficiently large, thermal promotion of the electron or hole to the conduction band or valence band, respectively, is improbable at the irradiation temperature, and so these charge carriers remain trapped after irradiation. However, if the sample is then heated, thermally assisted recombination becomes increasingly probable, and the result is an initially increasing light output with increasing temperature until the traps are depleted, whereupon the light intensity drops. The curve of light intensity versus temperature $I(T)$ is known as a glow curve, and may be analysed to extract the trap depths and concentrations. A comprehensive review of the field has been given by *McKeever* [40.7], and a shorter discussion is given by *Vij* [40.1].

The process is shown schematically for a simple system comprising a single electron trapping level T and a single recombination centre R in Fig. 40.5.

Irradiation results in a trapped electron at trap T and a trapped hole at R . The trapped hole binding energy is larger than that of the trapped electron, so the latter is depopulated first, with a probability P which has the form,

$$P = s \exp(-E/kT), \quad (40.7)$$

where s and E are the attempt frequency and the activation energy respectively. We have shown the hole trap and recombination centre as being one and the same in Fig. 40.5, but it is also possible that the recombination energy is transferred to a separate luminescent centre.

In the measurement process, the sample is heated at a fast and linear rate, typically 1–10 K/s, whilst the light emission is monitored by a sensitive filter/photomultiplier combination, or by a monochromator system. The resulting glow curve may be fitted to a theoretical curve to extract the trap parameters. Generally the light output is quite weak, and TSL systems have sensitivity as one of their prime design factors, so cooled detectors and photon counting are commonplace. Above about 400 °C, thermal radiation from the sample/heater

is a problem and must be eliminated by filtering or by subtraction of a glow curve recorded using a thermally bleached sample.

The main uses of TSL are in determining trap depths and irradiation doses. In archaeological and geological applications, a comparison is made between accumulated natural dose and a dose from a radioisotope; by combining this with a measurement of the activity of the surroundings, a date since last thermal or optical erasure

Fig. 40.5 Thermally stimulated luminescence process

Fig. 40.6 Computed glow curves for first-order kinetics for fixed escape frequency and various trap depths

of the object can be determined. The nature of the traps is often poorly understood for these chemically complex samples. For medical dosimetry, room-temperature stable traps with high thermoluminescent output are required. At present, the material of choice is LiF doped with a few hundred ppm of Mg and Ti.

The mathematical form of the TSL glow curve depends on the physical model used for the TL process. In the simplest case, assuming first-order kinetics [40.1, 7], the light intensity I at temperature T is given by,

$$I(T) = n_0 s \exp(-E/k_B T) \times \exp \left[- (s/\beta) \int_{T_0}^T \exp(-E/k_B T) dT \right], \quad (40.8)$$

where n_0 is the number of occupied traps at time $t = t_0$ when the temperature is T_0 , β is the heating rate in K/s, and k_B is Boltzmann's constant. The result is a glow curve whose peak position varies approximately linearly with trap depth E , as shown in Fig. 40.6 (for fixed escaped frequency $s = 3.3 \times 10^{11} \text{ s}^{-1}$ and heating rate 1 K/s).

Of course, the peak position also depends on the escape frequency s , but is less sensitive to s than to E . For second-order kinetics [40.1, 7], the glow curve equation becomes

$$I(T) = \left(n_0^2 s / N \right) \exp(-E/k_B T) / \left[1 + (n_0 s / N \beta) \int_{T_0}^T \exp(-E/k_B T) dT \right]^2, \quad (40.9)$$

Fig. 40.7 Comparison of first- and second-order glow curves

where N is the number of available traps. The two forms both give glow curves of similar shape, but the first-order form shows an asymmetric form with a sharp fall off on the high-temperature side of the peak, whilst the second-order form is more symmetric as shown in Fig. 40.7. The parameters are extracted by least-squares fitting of these expressions to the experimental glow curves, which is cumbersome due to the integral, but *Kitis* et al. [40.8] have given analytical approximations to (40.8) and (40.9). In practice, many glow curves do not follow first- or second-order kinetics precisely.

40.4 Optically (Photo-)Stimulated Luminescence

Thermally stimulated luminescence is sometimes also accompanied by optically stimulated luminescence (OSL), in which one of the trapped carriers is excited by optical stimulation to a level from which it can recombine with the conjugate carrier by tunnelling, or completely to one of the bands so that recombination is achieved through what is essentially a photoconductivity effect. For OSL to be significant,

there must be an appreciable optical transition probability, so not all TSL centres are OSL active. The stimulation energy measured in OSL generally differs from that determined from TSL because of the Franck–Condon principle. The OSL effect finds practical application in dosimetry, e.g. [40.9], and in X-ray storage phosphors used for medical imaging, as described later.

40.5 Experimental Techniques – Photoluminescence

A typical traditional photoluminescence measuring system involves a broad-spectrum source, either a combined tungsten filament for the visible spectrum and deuterium lamp for the UV, or a xenon flash lamp. The lamp emission is passed through a grating monochromator and so selectively excites the luminescence. Band-pass or band-edge filters are generally required to eliminate unwanted second- and higher-order diffraction maxima from the grating. The luminescence is efficiently gathered by low- f /number optics and fed to a second grating monochromator, also equipped with filters, to monitor and analyse the luminescence. The final detector may be a photomultiplier, or preferably a charge-coupled device or photodiode array for improved data collection efficiency at multiple wavelengths.

This arrangement relies on good monochromatization/filtering to remove what is sometimes a relatively strong component of scattered light from the beam analysed by the emission monochromator. An alternative method of removing scattered light is to use time discrimination, by replacing the source by a xenon flash lamp (for example, as in the common Perkin Elmer LS55B luminescence spectrometer). The flash has a duration of about 10 μ s, so any scattered light has decayed away to an insignificant level when the emitted beam is sampled some time (0.1–10 ms) after the flash. A timed electronic gate is used to sample the emission immediately after a flash and just before the next flash; the difference between these two sampled signals gives the short-term luminescence whilst the second sample alone gives the long-term luminescence with *long* and *short* being relative to the flash repetition period. Of course, luminescence with lifetimes shorter than the pulse width ($\approx 10 \mu$ s) cannot be readily measured with this system. The luminescence intensity is normalised with respect to the excitation intensity by steering a sample of the excitation beam to a rhodamine dye cell which has a quantum efficiency of essentially unity for wavelengths below about 630 nm. The fluorescence from the dye is measured with a second photomultiplier.

To minimise the effect of scattered light, a conventional laser with its intrinsically narrow linewidth and high intensity is a very convenient replacement for a broad-spectrum lamp, but suffers from the disadvantage of a fixed wavelength. Typical lasers of interest are nitrogen (pulsed), argon (UV lines, or frequency-doubled visible lines), krypton, and the new

generations of GaN/GaInN blue/violet/UV laser diodes. For rare-earth spectroscopy, or other systems which are characterised by narrow absorption lines, it is very useful to have a scanning dye laser as the excitation source. This *selective excitation* facility enables *tagging* of particular luminescent levels with excited states belonging to the same centre, so that a picture of the energy-level structure of each luminescent centre can be built up in cases where several such centres contribute to the overall luminescence.

For decay kinetics on faster time scales, fluorimeters such as those developed initially by the Spex company (now Horiba) use a fast modulator and phase-sensitive detection to measure the phase shift between fluorescence and excitation; it is claimed that fluorescence decays can be measured with a resolution of 25 ps this way. An alternative is the time-correlated single-photon-counting technique which can measure decay constants in the ps–ns range. In this method, the excitation comes from a fast laser pulse, and the light level reaching the photomultiplier or micro-channel plate detector is reduced to such a low level that less than one photon per excitation pulse is detected. The time delay between the photon detection and the time of the pulse is measured, and a histogram produced of numbers of detected photons versus arrival time taken over a large number of excitation pulses. For efficient data collection, a high repetition rate and fast-pulse laser are required, often a Ti–sapphire laser. The wavelength for Ti–sapphire is too large for stimulating many materials directly with single-photon excitation, but stimulation is nonetheless possible by a two-photon excitation process, or by the use of a nonlinear crystal acting as a frequency doubler to produce laser output at one half the wavelength of the basic laser.

There are a number of specialist techniques, such as hole-burning, fluorescence line-narrowing, and photon echo methods associated with the use of lasers with either very narrow line widths or short pulse duration which have developed in a parallel way to techniques first introduced in nuclear magnetic resonance, and which are mainly used to investigate the dynamics and quantum mechanics of the luminescent species rather than the material in which they are contained. *Meijerink* gives a review of experimental luminescence techniques [40.1] which includes a short discussion of these specialist techniques.

40.6 Applications

The largest market for luminescent materials has traditionally been in the areas of lighting, through fluorescent tubes, and in cathode-ray-tube screen phosphors for image display. Both of these areas can now be regarded as mature in terms of materials development. However, new discoveries in the past decade, and the advent of new technologies, have rekindled interest in phosphor materials. Some of the current areas of activity in applications are outlined below.

40.6.1 White Light-Emitting Diodes (LEDs)

The development of blue, violet and UV LEDs based on GaN, InGaN and other semiconductors and alloys has stimulated great interest in the possibility of producing a *white-light LED* for use in lighting applications. LEDs are now available with emissions which peak as low as 365 nm in the ultraviolet. The concept is to use the blue emission to stimulate luminescence from yellow, or red and green phosphors, so that when mixed with residual blue light from the LED the result is simulated white light. For UV LEDs the LED output is used to stimulate blue, red and green phosphors.

The first generation of white LEDs from companies such as Nichia relied on a YAG:Ce phosphor to convert

some of the emission from a 465-nm GaInN LED into an orange/yellow emission centred at 550 nm; the combination of blue and yellow simulates white light. More recent versions of this scheme include $\text{Sr}_3\text{SiO}_5:\text{Eu}^{2+}$, which emits at 570 nm, and is claimed [40.10] to be more efficient than YAG:Ce, and a $\text{CaSiAlON}:\text{Eu}$ ceramic phosphor which offers improved thermal stability [40.11]. Improved colour rendition is obtained by using more phosphors and better balance between the various emissions, for example by replacing the YAG:Ce with $\text{SrGa}_2\text{S}_4:\text{Eu}$ (green) and $\text{SrY}_2\text{S}_4:\text{Eu}$ (red). Most recent developments based on 375 nm UV LEDs have used multiple emissions to achieve even better colour balance; for example Kim et al. [40.12] use $\text{Sr}_3\text{MgSi}_2\text{O}_8:\text{Eu}^{2+}$, Mn^{2+} , which has blue (Eu^{2+}), yellow (Eu^{2+}) and red emissions (Mn^{2+}).

A second development in this area is the substitution of another semiconductor for the phosphor – the so-called photon recycling technique. In this method, a layer of AlGaInP is used to absorb some of the blue incident radiation and down-convert it to the complementary colour. The advantage is that the fabrication/integration process is simpler compared to combining phosphor and semiconductor technology.

Fig. 40.9 Excitation and emission spectra of a commercial lighting strip based on Nemoto $\text{SrAl}_2\text{O}_4:\text{Eu}/\text{Dy}$ material

40.6.2 Long-Persistence Phosphors

It has been discovered in the past decade that some materials show a very long-lived but intense afterglow, arising from thermal emission of charge carriers from deep traps, followed by electron–hole recombination at or near a luminescent ion, i.e. room-temperature thermoluminescence. The persistence is for periods of several hours, much longer than the well-known ZnS:Cu persistent phosphor. This new class of materials have widespread applications in areas such as signage and passive emergency lighting for public buildings, aircraft cabins etc. The material is activated or *charged* by the blue/UV content of solar radiation or fluorescent indoor lighting during normal conditions; in subsequent dark conditions the energy is released as an afterglow. No power supply is required, the operation is entirely passive, and so a high degree of reliability is assured. Generally the phosphor powder ($\approx 10\ \mu$ grain size) is mixed with a resin binder and applied as a thick ($\approx 1\text{ mm}$) coating. The materials which have been used are rare-earth-doped strontium or calcium aluminate [CaAl_2O_4 :Eu/Nd (blue), SrAl_2O_4 :Eu/Dy (green), $\text{Sr}_4\text{Al}_{14}\text{O}_{25}$:Eu/Dy (blue–green), and $\text{Y}_2\text{O}_2\text{S}$:Eu/Mg/Ti (orange)]. Figures 40.8 and 40.9 show the decay and emission/excitation characteristics of a commercial phosphor strip of this type, based on Luminova® SrAl_2O_4 :Eu/Dy powder sourced from the Nemoto company. The decay is clearly non-exponential, but after the initial rapid decay the intensity may be fitted with an exponential with a decay constant of 3.1 h.

The traps which are responsible for the long-lived decays in these systems have not been clearly identified, and it is likely that there are several involved. Jia et al. [40.13, 14] have studied persistent violet/UV and blue ($\approx 400\text{ nm}$, 450 nm) luminescence from rare-earth ions in CaAl_2O_4 and BaAl_2O_4 and report that the thermally stimulated luminescence from these materials contains multiple glow peaks. They also describe how co-doping the calcium aluminate with Tb^{3+} results in a green persistent phosphor as a result of energy transfer from the cerium to the terbium ion; this mechanism could be the basis for convenient colour control, including white persistent phosphors. Aitasalo et al. [40.15] report that the nature of the traps is affected by the particular rare-earth ion or couple.

40.6.3 X-Ray Storage Phosphors

Optically stimulated or photo-stimulated luminescence is the basis for an X-ray imaging technology known

commercially as computed radiography (CR). CR was the first of a number of imaging techniques which are steadily replacing traditional photographic film methods. Several other techniques such as those based on amorphous selenium photoconductor/flat panels and a-Si arrays, and scintillator CCD/complementary metal–oxide–semiconductor (CMOS) arrays have also emerged in recent years, but CR is still the dominant of the new technologies on the basis of numbers of installed units. The many advantages of CR over photographic film, and the principles of the method are detailed in [40.16, 17], but the basic mechanism is that incident X-rays create electron–hole pairs in the material. Most of these promptly recombine, but some are trapped at defects and impurities, and remain trapped for periods of hours after the X-ray source is turned off. In an X-ray storage phosphor (XRSP), one of the trapped carriers is optically stimutable, and can be excited to the conduction band or valence band, or to a level from which it can recombine by tunnelling with the conjugate trapped carrier. The resulting recombination energy is transferred to a luminescent ion, and the intensity of the photo-stimulated luminescence (PSL) is in direct proportion to the incident X-ray intensity. The dominant material used in current XRSP systems is $\text{BaFBr}_{1-x}\text{I}_x\text{:Eu}^{2+}$, where the electron traps are F-centres, the hole traps are unidentified, and the luminescence is the $5d\text{--}4f$ transition of the Eu^{2+} ion. One disadvantage of systems based on this (powder) phosphor is that when the image is extracted with a raster-scanned He–Ne laser beam, light scattering from the powder grains means that material outside the focussed laser spot is also stimulated, limiting the spatial resolution to around $200\ \mu\text{m}$, which is inadequate for applications such as mammography. Several ways to overcome this are currently under development. RbBr:Eu is also an X-ray storage phosphor [40.18] and can be grown by vapour deposition in a columnar form.

Fig. 40.10 PSL image of a BC549 transistor recorded on a glass-ceramic imaging plate

The columnar structure has a light-guiding property, restricting the scattering effect, and improving the resolution. A second development is that of glass-ceramic storage phosphors, where PSL active crystals are embedded in a glass [40.19–21]; the combination of particle size, separation and refractive-index mismatch means that these composite materials are semitransparent and the problem of scattering of read-out light is reduced. Figure 40.10 shows an image of a BC549 transistor recorded in a glass-ceramic X-ray storage phosphor.

40.6.4 Phosphors for Optical Displays

There are several new technologies being developed to replace cathode ray tubes for domestic televisions, including plasma display panels (PDPs). In these units, each pixel is a sealed cell containing a mixture of Xe and Ne in a dielectric-shielded electrode structure (for a review, see Boeuf [40.22]). An alternating current (AC) voltage applied between the electrodes results in a glow discharge being set up in the gas, and a Xe dimer vacuum UV (VUV) emission predominantly between 147 and 190 nm occurs. (In comparison, the mercury discharge in a conventional fluorescent tube emits primarily at 254 nm.) The UV discharge excites red, blue, or green phosphors coated on one of the cells; each colour is activated by an adjacent electrode. The requirements for efficient output from these phosphors differ from conventional tubes since the latter were chosen on the basis of their luminescence efficiency at a 254-nm pump wavelength, and their resistance to degradation by the UV light and chemical attack by Hg^+ ions. These requirements are evidently different for the PDP technology; in addition the phosphors must have a significant reflection coefficient in the visible to optimise the light output [40.23], and the surface quality is of greater significance due to the short penetration depth of the VUV. The phosphors which have been used so far include $\text{BaMgAl}_{10}\text{O}_{17}:\text{Eu}^{2+}$ (blue), $\text{Zn}_2\text{SiO}_4:\text{Mn}^{2+}$ (green), and $(\text{Y}, \text{Gd})\text{BO}_3:\text{Eu}^{3+}$ and $\text{Y}_2\text{O}_3:\text{Eu}^{3+}$ (red). The blue phosphor is prone to degradation.

The widespread introduction of Xe excimer excitation in PDPs can be expected to stimulate applications in other lighting technologies. In this regard, the possibility of so-called *quantum cutting* is of much interest. This recognises that the energy of a VUV photon is equivalent to two or more visible photons, so that quantum efficiencies in excess of 100% can in principle be achieved. The difficulty lies in finding a luminescent ion system whose energy-level system provides for both efficient pumping and two-photon luminescence in the visible. One

example which has been reported to have a quantum efficiency of up to $\approx 145\%$ is Pr^{3+} in YF_3 and other hosts [40.24, 25], where the excitation is through the allowed $4f^2 \rightarrow 4f^1 5d^1$ or host transitions. The system then decays to the $^1\text{S}_0$ excited state of the $4f^2$ configuration from which two-photon decay is possible through successive $^1\text{S}_0 \rightarrow ^1\text{I}_6$ and $^3\text{P}_0 \rightarrow ^3\text{H}_J, ^3\text{F}_J$ transitions, as shown in Fig. 40.2. (The intermediate step from $^1\text{I}_6$ to $^3\text{P}_0$ is provided by a nonradiative transition.) A difficulty is that the photon for the first transition is in the UV region of the spectrum, and so it is necessary to incorporate a second luminescent ion pumped by this transition to convert the UV to visible output, and the visible quantum efficiency is necessarily reduced.

40.6.5 Scintillators

Although semiconductor detectors of ionising radiation are making increasing inroads into the particle detection market, traditional scintillators are still widely used and are indispensable for some applications. The operating principle is that an incident gamma ray creates a large number of electron–hole pairs in the scintillating material directly or indirectly through the photoelectric effect, Compton scattering, or pair production, and that some of the energy of recombination appears as photon emission from luminescent ions. Charged particles such as protons produce electron–hole pairs through the Coulomb interaction with the band electrons. The *scintillation* or multiphoton bursts which signal the event is detected by a photomultiplier, and the height of the output pulse from the photomultiplier is proportional to the energy of the particle. A pulse-height analyser sorts the pulses according to energy, and so an energy spectrum can be obtained. Key figures of merit for a scintillator material are the numbers of photons per MeV of particle energy, the radiative lifetime of the luminescent ion (since possible pulse overlap limits the maximum count rate which can be measured), and the weighted density ρZ_{eff}^4 , which reflects the gamma sensitivity. (Here Z_{eff} is the effective atomic number.) A recent review of scintillators has been given by van Eijk [40.26]. The most widely used scintillator for many years has been $\text{NaI}:\text{Tl}$, but many different scintillators are being investigated, driven by the need for improved performance and lower cost for medical applications such as positron emission tomography (PET) and single-photon emission computed tomography (SPECT), and for large-scale elementary-particle facilities such as those at the Centre Européen pour la Recherche Nucléaire (CERN). In the latter regard, the Crystal Clear collaborative project and other programs

have resulted in several new materials such as LaBr_3 , LaCl_3 , Lu_2SiO_5 , Gd_2SiO_5 , and LuAlO_3 , all Ce-doped, and undoped $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ and PbWO_4 , with typical performance figures of 10 000–50 000 photons/MeV and lifetimes of 10–50 ns. For gamma spectroscopy the pulse-height resolution is critical and $\text{LaBr}_3\text{:Ce}$ has twice the resolution of NaI:Tl . The fastest scintillators

are based on core-valence luminescence where a hole created in a core level recombines with an electron in the valence band. For example, BaF_2 shows this *cross-luminescence* effect with a lifetime as short as 600 ps. The effect is only shown by materials with a core-valence (CV) band energy gap less than the usual band gap, otherwise CV luminescence is absorbed.

40.7 Representative Phosphors

To conclude, we present in Table 40.2 a list of several luminescent materials of practical significance. The table is intended to be representative rather than comprehensive.

It is noticeable from the table that just a few ions are responsible for a large number of applications, and primarily as oxides.

Table 40.2 Some luminescent materials of practical significance

Host	Dopants	Colour	Excitation	Application
$\text{Bi}_4\text{Ge}_3\text{O}_{12}$	–	Blue	Ionising radiation	Scintillator
ZnS	Ag^+	Blue	Electrons	Colour TV screens
$\text{Zn}_{0.68}\text{Cd}_{0.32}\text{S}$	Ag^+	Green	Electrons	Colour TV screens
$\text{Y}_3\text{Al}_5\text{O}_{12}$	Ce^{3+}	Yellow	Blue, violet	White LED
Gd_2SiO_5	Ce^{3+}	UV	Ionising radiation	Scintillator
ZnS	Cu^+	Green	Electrons	Colour TV screens
BaFBr	Eu^{2+}	UV/blue	X-rays	X-ray imaging
$\text{BaMgAl}_{10}\text{O}_{17}$	Eu^{2+}	Blue	UV	fluorescent lamps, plasma displays
Sr_3SiO_5	Eu^{2+}	Blue	UV	White LED
SrGa_2S_4	Eu^{2+}	Green	UV	White LED
SrAl_2O_4	Eu^{2+} , Dy^{3+}	Green	UV, violet	Persistent phosphor
CaAl_2O_4	Eu^{2+} , Nd^{3+}	Blue	UV, violet	Persistent phosphor
Y_2O_3	Eu^{3+}	Red	Electrons, UV	Colour TV screens, fluorescent lamps
Sr_2SiO_4	Eu^{3+}	Yellow	UV	White LED
$(\text{Y}, \text{Gd})\text{BO}_3$	Eu^{3+}	Red	UV	Plasma displays
Y_2O_3	Eu^{3+}	Red	UV	Plasma displays
SrY_2S_4	Eu^{3+}	Red	UV	White LED
LiF	Mg^{2+} and Ti^{4+}	UV/blue	Ionizing radiation	TL dosimetry
ZnS	Mn^{2+}	Yellow	Electric field	Panel displays
Zn_2SiO_4	Mn^{2+}	Green	UV	Plasma displays
$\text{CeMgAl}_{11}\text{O}_{19}$	Tb^{3+}	Green	UV	Fluorescent lamps

41. Nano-Engineered Tunable Photonic Crystals in the Near-IR and Visible Electromagnetic Spectrum

Photonic crystals offer a well-recognized ability to control the propagation of modes of light in an analogous fashion to the way in which nanostructures have been harnessed to control electron-based phenomena. This has led to proposals and indeed demonstrations of a wide variety of photonic-crystal-based photonic devices with applications in areas including communications, computing and sensing, for example. In such applications, photonic crystals can offer both a unique performance advantage, as well as the potential for substantial miniaturization of photonic systems. However, as this review outlines, two-dimensional (2-D) and three-dimensional (3-D) structures for the spectral region covering frequencies from the ultraviolet to the near-infrared ($\approx 2\mu\text{m}$) are challenging to fabricate with appropriate precision, and in a cost-effective and also flexible way, using traditional methods. Naturally, a key concern is how amenable a given approach is to the intentional incorporation of selected defects into a particular structure. Beyond passive structures, attention turns to so-called active photonic crystals, in which the response of the photonic crystal to light can be externally changed or

tuned. This capability has widespread potential in planar lightwave circuits for telecommunications, where it offers mechanisms for selective switching, for example. This review discusses alternative proposals for tuning of such photonic crystals.

Photonic crystals (PCs) are periodic, dielectric, composite structures in which the interfaces between the dielectric media behave as light-scattering centers. PCs consist of at least two component materials having different refractive indices, and which scatter light due to their refractive-index contrast. The one, two, or three-dimensional (1-D, 2-D, or 3-D) periodic arrangement of the scattering interfaces may, under certain conditions, prevent light with wavelengths comparable to the periodicity dimension of the PC from propagating through the structure. The band of forbidden wavelengths is commonly referred to as a *photonic band gap* (PBG). Thus, PCs are also commonly referred to as photonic-band-gap (PBG) structures.

PCs have great potential for providing new types of photonic devices. The continuing demand for photonic devices in the areas of communications, computing, and signal processing, using photons as information carriers, has made research into PCs an emerging field with considerable resources allocated to their technological development. PCs have been proposed to offer a means for controlling light propagation in submicron-scale volumes – the photon-based equivalent of a semiconductor chip – consisting of optical devices integrated together onto a single compact circuit. Proposed applications of PCs for the telecommunication sector include optical cavities, high-*Q* filters, mirrors, channel add/drop filters, superprisms and com-

pact waveguides for use in so-called planar lightwave circuits (PLCs).

Practical applications of PCs generally require man-made structures, as photonic devices are designed primarily for light frequencies ranging from the ultraviolet to the near-IR regime (i. e., ≈ 100 nm to ≈ 2 μ m, respectively) and PCs having these corresponding periodicities are not readily available in nature. 1-D PCs in this wavelength range may be easily fabricated using standard thin-film deposition processes. However, 2-D and 3-D PC structures are significantly more difficult to fabricate and remain among the more challenging nanometer-scale architectures to realize with cost-effective and flexible patterning using traditional fabrication methodologies. Recently, there has been considerable interest in PC-based devices that has driven advanced fabrication technologies to the point where techniques are now available to fabricate such complex structures reliably on the laboratory scale. In addition to traditional semiconductor nanostructure patterning methods based on advanced patterning/etching techniques developed by the semiconductor industry, novel synthesis methods have been identified for 2-D and 3-D periodic nanostructured PC arrays. There are several excellent reports reviewing these fabrication techniques in the literature [41.1–4] and this growing field has already

been the subject of numerous recent reviews, special issues, and books in the area of theoretical calculations (both band-structure and application simulations), 2-D PC structures, 3-D PC structures, and opal-based structures [41.5].

Recently, there has been great interest in exploring the use of PCs for active applications in the field of telecommunications, such as in the area of PLCs (e.g., for optical switching). In such applications, the PC properties should be adjustable to create *tunable* photonic band gaps. This development increases the functionality of all present applications of PCs by allowing the devices in such applications to be adjustable, or tunable. We review recent developments in the engineering of tunable nanometer-scale architectures in 2-D and 3-D. This review aims to organize this ever-changing volume of information such that interested theorists can design structures that may be easily fabricated with certain materials, and such that technologists can try to meet existing fabrication gaps and issues with current systems.

The chapter begins with a brief introduction to PCs, followed by general criteria used to determine appropriate methodologies for the nano-engineering of tunable PCs. Finally, overviews of the most common fabrication methods for tunable 2-D and 3-D PCs will be given.

41.1 PC Overview

41.1.1 Introduction to PCs

The simplest PC structure is a multilayer film, periodic in 1-D, consisting of alternating layers of material with different refractive indices (Fig. 41.1). Theoretically, this 1-D PC can act as a perfect mirror for light with wavelengths within its photonic band gap, and for light incident normal to the multilayer surface. 1-D PCs are found in nature, as seen for example in the iridescent colors of abalone shells, butterfly wings and some crystalline minerals [41.6], and in manmade 1-D PCs (i. e., also known as Bragg gratings). The latter are widely used in a variety of optical devices, including dielectric mirrors, optical filters and in optical fiber technology.

The center frequency and size (i. e., frequency band) or so-called stop band of the PBG depends on the refractive index contrast (i. e., n_1/n_2 , where n_1 and n_2 represent the refractive index of the first and second material, respectively) of the component materials in the system. Figure 41.1 is an example of a 1-D PC, with a pe-

riodic arrangement of low-loss dielectric materials. This multilayer film is periodic in the z -direction and extends to infinity in the x - and y -directions. In 1-D, a photonic band gap occurs between every set of bands, at either the edge or at the center of the Brillouin zone – photonic band gaps will appear whenever n_1/n_2 is not equal to unity [41.7]. For such multilayer structures, corresponding photonic band gap diagrams show that, the smaller the contrast, the smaller the band gaps [41.7]. In 1-D PCs, if light is not incident normal to the film surface, no photonic band gaps will exist. It is also important to note that, at long wavelengths (i. e., at wavelengths much larger than the periodicity of the PC), the electromagnetic wave does not probe the fine structure of the crystal lattice and effectively sees the structure as a homogeneous dielectric medium.

The phenomena of light waves traveling in 1-D periodic media was generalized for light propagating in any direction in a crystal, periodic in all three dimensions, in 1987 when two independent researchers suggested that

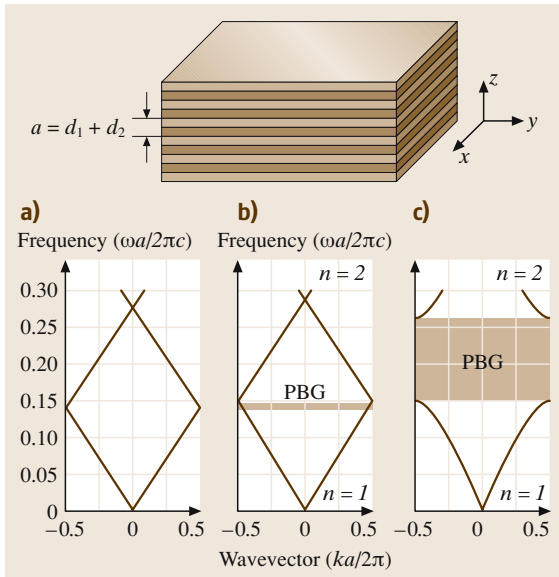

Fig. 41.1a–c Example of a 1-D photonic crystal. For a structure with $d = 0.5a$, the corresponding band gap diagrams are shown for: **(a)** GaAs bulk ($\epsilon = 13$); **(b)** GaAs/GaAlAs multilayer ($\epsilon_1 = 13$, $\epsilon_2 = 12$); and **(c)** GaAs/air multilayer ($\epsilon_1 = 13$, $\epsilon_2 = 1$) (from [41.7])

light propagation in 3-D could be controlled using 3-D PCs [41.8,9]. By extending the periodicity of the 1-D PC to 2-D and 3-D, light within a defined frequency range may be reflected from any angle in a plane (in 2-D PBG structures) or at any angle (in 3-D PBG structures).

Since the periodicity of PCs prevents light of specific wavelengths (i. e., those within the photonic band gap) from propagating through them in a given direction, the intentional introduction of *defects* in these structures allows PCs to control and confine light. Propagation of light with wavelengths that were previously forbidden can now occur through such defect states located within the photonic band gap. Defects in such PCs are defined as regions having a different geometry (i. e., spacing and/or symmetry) and/or refractive-index contrast from that of the periodic structure. For example, in a 2-D PC consisting of a periodic array of dielectric columns separated by air spaces, a possible defect would include the removal of a series of columns in a line. Specific wavelengths of light forbidden from propagating through defect-free regions would then be able to propagate through the line defect, but not elsewhere. Indeed, by appropriately eliminating further columns, light may be directed to form optical devices, including, for example, a low-loss 90° bend in a 2-D

Fig. 41.2 Theoretical simulation of a low-loss 90° bend in a 2-D waveguide [41.7]

waveguide, as shown by theoretical simulation [41.7] (Fig. 41.2).

Clearly, photons controlled and confined in small structures, with size on the order of the wavelength of light, using the extremely tight bend radii offered by PCs would facilitate miniaturization and the fabrication of PLCs [41.7]. In addition, since the periodicity of the PC gives rise to the existence of band gaps which change the dispersion characteristics of light at given frequencies, defect-free PCs give rise to other interesting phenomena, including highly dispersive elements, through the so-called superprism effect [41.10]. Possible designs of PC-based optical devices using such properties have been extensively explored [41.1, 11], generating much excitement in the field of optical telecommunications [41.6].

41.1.2 Nano-Engineering of PC Architectures

Most of the promising applications of 2-D and 3-D PCs depend on the center frequency and frequency range of the photonic band gaps. A so-called *complete, full, or true* PBG is defined as one that extends throughout the entire Brillouin zone in the photonic band structure – that is, for all directions of light propagation for photons of an appropriate frequency. An incomplete band gap is commonly termed a *pseudo-gap* or a *stop band*, because it only occurs for reflection/transmission along a particular propagation direction. A complete gap occurs when stop-band frequencies overlap in all directions in 3-D. The center frequencies and stop-band

Fig. 41.3 PBG parameters that affect the center frequency and associated stop band (shown in *top view*, in *boxes*) relative to the 2-D periodic arrangement of one material (i. e., the rods, in *grey*) embedded in a second material (i. e., air), periodic in the x - y plane (shown in the *central figure*)

locations of the PBGs critically depend on the unit-cell structure [41.7–9, 12, 13]. In particular, the PC properties depend on the symmetry of the structure (i. e., the unit-cell arrangements), the scattering element shape within the unit cell, the fill factor (i. e., the relative volume occupied by each material), the topology, and the refractive-index contrast (Fig. 41.3).

It has been shown that a triangular lattice with circular-cross-section scattering elements in 2-D, or a face-centered-cubic/diamond lattice with spherical scattering elements in 3-D, tend to produce larger PBGs [41.7]. Also, as discussed above, the dielectric contrast is an important determining factor for 2-D and 3-D PC structures. The lower the dimension of the structure, the more readily a PBG manifested, since overlap of the PBGs in different directions is more likely (something which is a certainty in 1-D structures). In 3-D structures, calculations have determined that the minimum dielectric contrast (n_1/n_2) required to obtain a full PBG is about 2.0 [41.2, 12, 14]. For full PBGs, the ideal structure typically consists of a dielectric–air combina-

tion, to obtain both the greatest dielectric contrast as well as to reduce losses associated with light propagation in optical materials other than air [41.7].

The relationship between the fill factor, structure symmetry, and scattering element shape on the size and location of the PBG is complex [41.7, 15–18] and will not be discussed in detail here. However, it is clear that the ability to adjust, or tune, one or more of these parameters and thus tune the PC properties, is a very exciting development for future PC device applications.

41.1.3 Materials Selection for PCs

The physical architecture of a given PC is just one of the design considerations – another important one is the optical properties of the PC materials. In particular, the refractive index of a given material and its electronic band gap determine the performance and appropriate range of frequencies of PC devices fabricated from such a material.

For large PBGs, component materials need to satisfy two criteria; firstly, having a high refractive-index contrast, and secondly, having a high transparency in the frequency range of interest. This may be a challenge to satisfy at optical wavelengths. Suitable classes of PC materials include conventional semiconductors and ceramics, since at wavelengths longer than their absorption edge (or electronic band gap), they can have both high refractive indices and low absorption coefficients. In addition, these materials have other very useful electronic and optical properties that may complement the functions served by the presence of the PBG.

Another, often overlooked, consideration for PC material selection is the ability to translate the desired bulk single-crystal properties of well-known materials into nanometer-scale PC properties. Such structures typically have extremely large surface areas, and the microstructure of the constituent PC elements must be controlled during fabrication. Consequently, the final properties of the PC elements often vary from those of the bulk properties. This is extremely relevant when considering the functionality of a final PC device, such as those relying on electronic properties (e.g., lasing).

Finally, it is interesting to note that there is a strong correlation between the fabrication methods selected and the component materials. For example, top-down dry etching of semiconductors (e.g., Si, GaAs, InP, etc.) into nanostructured 2-D arrays is well characterized and relatively commonplace, whereas the same cannot be said for ceramic materials. The opposite is generally true for chemical or bottom-up synthesis using sol–gel

technology, in which ceramic PCs are relatively easy to fabricate when sol-gel-based infiltration techniques are used (e.g., in 3-D inverse opal fabrication). It is also

clear that the fabrication technique primarily determines the PC structure that can be fabricated, which in turn, determines the PC properties.

41.2 Traditional Fabrication Methodologies for Static PCs

Unlike for electrons, where there are natural length scales, for photons there is no such length scale [41.19]. This lack of an absolute length scale ensures that the physics of PCs is scalable: resizing the system rescales the energy in such a way that the spectrum, in units of c/a (where c is the speed of light and a is the lattice parameter of the PC), is independent of the system size [41.19]. Since $\omega/(2\pi c/a) = a/\lambda$, it is customary to use such dimensionless units to measure the photon energy [41.19]. Besides spatial scaling, there is also dielectric scaling – that is, there is no fundamental scale for ϵ . Two systems whose dielectric functions scale by a factor, $\epsilon'(\mathbf{r}) = \epsilon(\mathbf{r})/s^2$ have spectra that are scaled by the same factor: $\omega' = s\omega$, which means that increasing the dielectric function by a factor of four decreases the photon energy by a factor of two [41.19].

The apparent scalability of PCs is misleading because it suggests that PCs are truly size-independent, which in practice is not the case. As the size of the PC elements decrease, the effect of structural inhomogeneities become increasingly important, leading to inherent size limitations for particular architectures and for particular materials systems. This is most evident in changes in effective refractive index (e.g., due to the formation of inter-granular phases, surface oxides, etc.) and functionality.

2-D systems are increasingly being used for micro-photonic applications and consist of periodic repetitions of objects in a 2-D arrangement [41.19]. 3-D systems present a modulation in the third direction, such as a stack of spheres [41.19]. To date, 2-D and 3-D PCs have been fabricated using various approaches, including those based on electron-beam lithography, self-assembly and templating. The stringency of the requirements for a fabrication methodology, are dictated by the application of a given PC, in conjunction with associated requirements for material and architecture. Currently, there remains a great need for fabrication methods for mass production of nanometer-scale PCs, offering flexibility in material composition and design, while overcoming the low throughput of serial lithographic patterning, and the low reproducibility and material

restrictions of self-assembly methods. Many excellent reports reviewing these fabrication techniques are available in the literature [41.1–4]. For readers unfamiliar with traditional PC fabrication techniques, the following sections review typical 2-D and 3-D PC fabrication methods, based on lithography, self-assembly and hybrid techniques.

41.2.1 2-D PC Structures

Introduction to 2-D PBG Structures

The advantage of the 2-D PC structure is that, due to its planar form, it is easier to fabricate using existing lithographic methods, it retains its original single-crystal properties, and it can be simply integrated into desired PLC designs. However, there are specific design limitations that must be considered for 2-D PC structures. The main problem that has been identified both theoretically and experimentally is diffraction losses in the third dimension (i.e., for light directed out of the plane of the 2-D PC) [41.1, 2].

Calculations often assume a perfect and infinite 2-D material. However, the aspect ratio in experimental structures fabricated using typical micromachining techniques (e.g., reactive-ion etching) tend to be very limited [41.2]. Thus, in order to confine light in the third dimension (i.e., the out-of-plane dimension), the structure must either be large compared to the beam size (i.e., many wavelengths deep), or must be sufficiently confined within a waveguide to experience the full interaction with the periodic lattice [41.1]. As a consequence, 2-D PC structures are now typically fabricated in three principal forms: (1) a 2-D array of air holes in a dielectric (or dielectric pillars of very high aspect ratio in air), (2) a slab waveguide consisting of a 2-D array of holes perforating a thin membrane (with the membrane thickness approximately equal to the hole diameter) and (3) a heterostructure waveguide (i.e., similar to those used for confining light and carriers in semiconductor laser heterostructures) with holes drilled through the heterostructure [41.20]. New fabrication methodologies need to be able to address the fabrication issues for each of these three types of low-loss 2-D PC structures in

order to implement these structures in practical device applications.

2-D Lithographic PC Fabrication Methods

The majority of semiconductor PCs are synthesized using the advanced lithographic and etching capabilities developed for the semiconductor microelectronic industry [41.1, 2, 4, 21]. One major benefit of being able to fabricate PCs from single crystals using top-down lithography is that the properties (e.g., nonlinear electro-optic properties) are typically superior to those for polycrystalline structures produced using bottom-up (e.g., template-based) processes [41.22]. Utilizing the former materials enables significant modulation of the optical properties suitable for developing tunable PC devices. Also, in top-down fabrication, the optical and dielectric properties of the bulk material may be characterized before PC fabrication, allowing them to be more effectively modeled after PC fabrication. Indeed, semiconductor-based PBG structures made using lithographic processes tend to be more reproducible than self-assembled PC structures. Most importantly, there is much greater flexibility in the design and implementation of lithographically fabricated structures, and hence to implementing functional devices. Finally, PC-based PLCs are ideal for optical system integration.

For high refractive-index contrast (i.e., larger photonic stop bands), the preferred PBG structure is a topologically patterned substrate (i.e., an air-solid PC), which may be fabricated using multistep submicron machining based on lithography. In this process, a radiation-sensitive resist is patterned to transfer structures to the bulk material. The patterned resist is developed (i.e., the properties of the exposed material are changed), followed by etching and/or metal thin-film deposition to define features in the bulk material. The majority of submicron machining processes involve exposure of the resist with either electromagnetic radiation (e.g., optical, UV or X-ray photons) or charged particles (electrons, low-energy heavy ions, high-energy light ions) [41.23]. Although resist exposure is essentially a surface micromachining technique and therefore planar, various wet and dry etching techniques have been successfully used to produce topologically varying microstructures in the axial direction [41.23].

Similar to all resist-based processes, the resist itself limits the ultimate minimum size and maximum density of nanostructured patterns [41.24, 25], and organic residues (from processes resist) are often sources of contamination [41.26]. Organic resists are chosen as a compromise between sufficient resilience for selected

postprocessing procedures, and having sufficiently high sensitivity and contrast (i.e., a low energy threshold for resist exposure and total resist exposure occurring only above a certain energy threshold with no resist exposure occurring below, respectively) to the incident exposure [41.27] – this tends to be a difficult compromise to satisfy in practice for traditional resist materials.

Lithographic methods provide a simple and straightforward approach for the intentional introduction of defects into these 2-D systems (due to the simple surface patterning), and this top-down method may be the only way to retain the bulk-like semiconducting properties that are required for certain functionalities (e.g., such as lasing).

Electromagnetic Radiation Patterning. Generally, using electromagnetic radiation to micromachine structures requires masks to expose a resist material in a spatially selective manner, with subsequent development of the exposed resist to produce microstructures. Masks typically incorporate multiple repeat patterns, enabling multiple microstructures to be fabricated in a single exposure, which significantly reduces costs [41.23]. Masks tend to be less useful for patterning with charged particles, since the high energy deposited into the mask during exposure can produce undesirable mask instabilities due to heat expansion, stress and damage [41.23]. Charged-particle micromachining is therefore normally limited to direct-write processes, where a focused charged-particle beam is scanned over a material in a specific pattern to produce microstructures. Such a direct-write process has the advantage of not requiring a mask, but suffers from relatively low throughput as a serial write process, and hence losses its attraction for multiple component production [41.23].

A main consideration of patterning approaches for PC fabrication is the minimum required feature size. Diffraction effects occurring for wavelengths of light below 100 nm impose a fundamental limitation on achievable structure sizes using optical lithography. Micromachined features smaller than about 250 nm are essentially beyond current readily available optical lithography systems [41.23], although recent advances (e.g., in UV lithography) will probably make this size regime achievable in the near future using a parallel patterning processes. Other techniques such as X-ray lithography that are capable of high-volume production, by allowing parallel exposure for larger-area nanometer-scale patterning, are hampered by challenges including making suitable high-resolution masks, as well as the significant capital cost required to achieve the high pho-

ton flux suitable for mass production of nanometer-scale components [41.23].

Charged-Particle Beams. Limitations on the minimum feature size using traditional photolithography have motivated a number of studies using serial patterning with charged-particle beams (e.g., electron-beam lithography (EBL) or, less commonly, focused ion-beam (FIB) lithography) to obtain the small feature sizes required in PC structures.

The advantages of EBL and FIB for defining sub-100-nm feature sizes in a mask-less fashion are offset by the fact that high-volume production is commercially impractical using such serial writing techniques [41.23, 28, 29]. Conventional ion implantation, though widely available and robust, has thus far been incapable of patterning densely organized nanostructures due to ion scattering [41.27, 30] and mask limitations [41.31–35].

Another consideration for choosing lithographic techniques for sub-100-nm-scale feature fabrication is that all the steps in this multistep process have their own limitations. Indeed, the finite size of the molecular compound comprising the resist sets the ultimate limit on pattern resolution [41.24, 36]. Since all traditional submicron micromachining techniques except FIB require resist exposure, this is a major factor for determining resolution – for example, the ultimate resolution of EBL is not determined by the electron optical system, which is ≈ 0.1 nm, but by the resolution of the resist and by the subsequent fabrication process [41.37]. Also, electrons in the beam scatter very easily from electrons in the resist material, and both scattered and secondary electrons cause a lateral spread in the patterned material due to diffusion effects (i.e., proximity effects) [41.23]. Thus, the very high spatial resolution achievable at the surface using EBL deteriorates as the beam penetrates into the resist, making EBL unsuitable for high-resolution topographically patterned structures using resist alone [41.23]. The advantage of mask-less processing for high-definition surface structures in resist and the inherently slower processing mean that EBL has been limited to mask-making and direct-writing on wafers for specialized applications such as fabrication of 2-D PCs for research purposes only [41.23].

Currently, the most commonly used method to fabricate 2-D PCs in the optical regime is EBL-based mask processing, combined with etching [41.1]. This approach has been used to pattern different semiconductor materials, including Si [41.4] and GaAs [41.1, 4, 7] (Fig. 41.4). Some detrimental effects arising from dry etching have been reported, including damage and ion

Fig. 41.4 Example of a 2-D PC structure in GaAs [41.7]. The air hole radius is 122.5 nm, the lattice parameter is 295 nm, and the holes are 600 nm deep

channeling that increase nonradiative recombination in active microstructures [41.1]. Other post-mask procedures used to fabricate 2-D PC structures include vertical selective oxidation and lift-off techniques [41.1]. In vertical selective oxidation, an *all solid* 2-D PC structure may be fabricated, which maintains the physical integrity of the crystal and allows deposition of electrical contacts afterwards. However, the oxidation process usually also occurs laterally, while typical desired configurations for 2-D PC crystals are structured in the vertical direction. Even with improved vertically selective oxidation techniques, the depth-to-diameter aspect ratios of pillars are around 1 : 1, which is significantly less than the 10 : 1 ratios achieved using dry etching techniques [41.1]. Also, volume shrinkage of up to 13% [41.1] can lead to strain, the formation of micro-cracks and other structural problems. 2-D PC membranes have been fabricated using epitaxial lift-off/substrate removal, but this method is limited to materials with sufficient wet-etch selectivity [41.1].

Despite its extremely low throughput, focused ion beams are presently used for direct, resistless, nanometer-scale surface modification, micromachining, and ion implantation. This is primarily because such patterning cannot be achieved with any other method. However, FIB patterning is inherently slow and expensive, and requires sophisticated optics for ion focusing. Also, the patterning resolution and proximity of nanometer-scale features is greatly limited by the significant FIB tail distribution [41.26, 36] and the highly dose-dependent sputtering yield of FIBs [41.38]. The use of FIB patterning has not been widely used to fabricate PCs.

Table 41.1 Summary of current submicron resist-based machining techniques [41.23]

Technique	Potential sub-100nm capability	Requires mask	Direct write	Facility availability	High-volume production capability	3-D capability
Optical lithography	No	Yes	No	Widespread industrial use	Yes	No ^a
X-ray lithography	Yes: depends on mask	Yes	No	Scarce and expensive	Yes	Yes
UV lithography	Yes: depends on mask	Yes	No	Scarce	Yes	Yes
Electron-beam writing	Yes: currently achieved	No	Yes	Medium availability	No	No
Low-energy ion beam writing	Yes: depends on focusing	No	Yes	Scarce	No	No ^b
High-energy ion beam writing	Yes: depends on focusing	No	Yes	Very scarce	No	Yes

^a Optical lithography is a surface technique. However, new supplementary dry etching techniques such as plasma etching are being used to produce submicron 3-D structures from 2-D surface structures in silicon

^b Low-energy ion-beam micro-machining (FIB) relies on sputtering atoms from the surface. 3-D structures can be produced by continuous erosion at a given location although, in practice, this is far too slow for practical 3-D microcomponent production.

Light ions collimated by stencil masks can be used to expose resists in a parallel fashion in both ion-projection lithography and masked ion-beam lithography [41.27]. The resist is exposed in a similar manner to X-ray and EBL. Light ions are generally preferred over heavier ions in ion lithography because they have the greatest range in resists (thick resists can be used to give low defect densities [41.31]), but protons also scatter more than heavier ions at the end of the implant range, limiting resolution and nanometer-scale feature proximity. However, the use of heavier ions to pattern, following the traditional approach used for semiconductor doping, can lead to mask erosion. This effect is negligible when light ions (e.g., hydrogen) are used, but can become pronounced for higher-dose implantation of heavier ions [41.27]. A summary of current lithography-based submicron micromachining techniques is given in Table 41.1.

2-D Self-Assembled PC Fabrication Methods

For 2-D PC structures, electrochemical methods (i.e., anodic etching and growth) and fiber-pulling have used to prepare extremely high-aspect-ratio ($\gg 50 : 1$) large-area nanometer-scale hole arrays (Fig. 41.5). These types of structures represent near-ideal infinite 2-D PC structures [41.20]. However, these methods are limited to specific materials (e.g., silicon [41.41] and alumina [41.39] for electrochemical methods, or glass [41.40] by fiber-pulling), and processes such as electrochemical etching are often limited in their capability to control fill factor, structure symmetry and scat-

Fig. 41.5a,b Examples of 2-D self-organized PC structures of: (a) NCA [41.39], (b) NCG (nano channel glass) [41.40]

tering element shape. 2-D PC structures with long-range periodicity obtained by electrochemical etching often require surface pre-patterning by serial lithography to obtain lattice dimensions in the visible to near-IR range.

Table 41.2 Parameters of current high-aspect-ratio 2-D periodic structures [41.42–44, 46]

Nanotemplate type	Alumina	Silicon	Glass
Pore size (nm)	1–10 ²	400–10 ⁴	> 10
Pore density (cm ⁻²)	10 ⁹ –10 ¹²	10 ⁶ –10 ⁹	10 ¹⁰
Pore arrangement	Pseudo-ordered ^a	Disordered ^a	Ordered
Thickness (nm)	10 ³	10 ³	10 ³
Temperature tolerance	< 450 °C	< 900 °C	< 600 °C

^a May be ordered using pre-patterning processes [41.42, 45]

Some examples of easily available, high-aspect-ratio nanoporous arrays include electrochemically grown porous alumina (nanochannel alumina, or NCA) [41.39], electrochemically grown silicon [41.42] and fiber-pulled nanochannel array glass (Table 41.2) [41.43, 44].

Nanochannel Alumina. NCA may be fabricated economically with well-characterized properties. Pseudo-ordered regions can be easily fabricated using electrochemical etching, compared with porous silicon, which requires back-side illumination in addition to an applied bias. The pore arrangement is completely disordered in silicon if no pre-patterning with optical or EBL is used [41.46].

Aluminium is electrochemically oxidized to alumina (Al₂O₃) under positive polarization. For over a century, the growth of disordered pore arrangements have been observed and studied for selected electrolytes that weakly dissolve alumina. However, in 1995 it was first discovered that, after an extended period of anodization, self-ordered porous alumina films with pores arranged in a hexagonal pattern are obtained at the growth front [41.39]. Although knowledge of how to fabricate such NCA templates is now widespread, the formation mechanism of hexagonal NCA has still not been completely elucidated. Mechanical stress between neighboring pores due to the volume expansion of alumina with respect to the aluminium substrate has been proposed as a mechanism for the self-ordering [41.46].

Controlled single-domain porous arrays may be obtained by lithographically pre-patterning the aluminium substrate, and applying the optimum potential for the corresponding inter-pore distance [41.47]. Recently, in addition to the hexagonal lattice, square and honeycomb lattices with square or triangular pore shapes have also been obtained by appropriate pre-patterning [41.48].

Extremely high-aspect-ratio NCA templates can be fabricated with periodicities ranging from ≈ 80 to ≈ 600 nm. The domain sizes (i. e., areas with the same orientations) are controlled by the anodization condi-

tions and increase with time to micrometer-scale sizes. The thickness of the NCA template can be controlled by the electrochemical etching time, from ≈ 50 nm to > 10 μ m thick.

Current Alternative 2-D PC Fabrication Methods.

Templating of 2-D Structures. 2-D PCs have been fabricated by templating a secondary material into a PC backbone, that can either remain in the final structure as a composite material or be removed to form a dielectric/air PC structure. In many cases, a dielectric/air PC structure is preferred due to the higher dielectric contrast, but depending on the original PC backbone material, it may not be possible for the secondary materials to be removed after templating.

Over the past decade NCA templates have been commonly used to fabricate various nanostructured arrays by either dry etching or by growth through templates [41.45, 49, 50]. This method of using self-assembled templates for nanostructure patterning has been used to pattern physical topology, resulting in either nanostructured hole arrays (e.g., by dry etching through the templates), or growth of nanostructured wire arrays [e.g., by metalorganic chemical vapor deposition (MOCVD), MBE, and chemical-solution deposition]. The effectiveness of NCA as a templating tool results from the fact that the alumina may be easily selectively chemically etched compared with semiconductor materials, and forms a robust mask for dry etching (compared to, for example, patterned resist materials).

Combining Self-Organized 2-D Structures with Ion Implantation. Ion-beam techniques may be used to pattern, for example, sub-100-nm-resolution features on thin membranes, but they are unsuitable for deep sub-surface patterning, particularly at the end of the implantation range. One reason for this is that stencil-type masks need to be used, due to the relatively short range of energetic ions compared to, for example, X-rays, which do not require stencil-type masks [41.24, 27]. In the

past, high-aspect-ratio stencil masks for ion implantation were fabricated using techniques such as EBL, but such stencil masks were limited by the low pattern density achievable using such fabrication methods, requiring the use of self-complementary masks with multiple offset exposures to create printed patterns [41.34]. Also, the minimum resolution using nanoscale ion implantation through masks is so sensitive to the mask's wall angle [41.32, 33] that advanced photoresists and lithographic techniques need to be used to achieve such ideal masks.

Investigations have been reported on new ways to combine self-organized 2-D PC structures with conventional, broad-beam ion implantation to achieve nanoscale pattern transfer [41.51, 52]. Using self-organized templates as masks significantly simplifies the process, as no resolution-limiting resist or no time-intensive serial patterning is necessary, and these ideal, stencil-type masks allow direct nanostructure array transfer with significantly less scattering than solid masks. The use of self-organized masks allows this process to be economically feasible for large-area nanostructure array patterning. This approach transfers the desired pattern from the self-organized template into a desired material that cannot be patterned on the same scale using self-organization.

Despite concerns about mask edge defects [41.53–55], extended radiation damage accumulation extending below the mask edges [41.30, 35] and possible mask distortion from stress and temperature [41.31], it has been shown that nanoscale features could be retained using conventional ion implantation combined with high-aspect-ratio masks to make PC-type structures [41.51, 52] (Fig. 41.6). Energetic, charged particles were accelerated into a substrate using broad-area parallel implantation through NCA templates to pattern 2-D nanostructured arrays of ions in both semiconductor (i.e., InP) and ceramic (i.e., SrTiO₃) single crystals [41.51, 52]. The ion-implanted volume was selectively etched away after implantation to form 2-D nanostructured air-hole arrays in the substrate material. The array pattern was successfully fabricated over the entire implant area ($\approx 1 \text{ cm}^2$), with resulting minimum feature sizes of $\approx 40 \text{ nm}$. Such a direct and parallel method, combining ion implantation with a nanoscale mask, can be immediately beneficial, particularly in applications where using FIB is impractically slow (e.g., for substrate nanostructure array pre-patterning for selective or electrochemical etching). In addition, complex profiles (e.g., membrane formation) were shown to be possible using this technique. This method allows ions to

be implanted into nanoscale areas, which may result in additional substrate modification, including, but not limited to, micromachining of implanted areas to fabricate topologically patterned nanostructured arrays.

The ability to process structures of different form and shape using ion-implantation techniques offers opportunities for nano-machining, and enables material processing on a nanometer scale – this is applicable to materials which cannot be structured using standard lithography (e.g., samples with pronounced topography [41.38]). This nanoscale patterning method can also be used to directly pattern substrates to create electrochemical initiation sites for fabrication of ordered porous Si and porous GaAs structures for light emission [41.56] and for 3-D PC fabrication in Si [41.57]. In addition, such array pattern transfer is applicable to pre-patterning of self-assembled templates themselves,

as a substitute for lithographic pre-patterning for the fabrication of ordered nanochannels in materials such as Si and Al_2O_3 [41.46].

41.2.2 3-D PC Structures

Introduction to 3-D PBG Structures

A main advantage of 3-D PBG structures over 2-D PBG structures is that the 3-D PBG structures can overcome the problem of diffraction losses in the third (out-of-plane) dimension [41.1, 2]. However, this advantage is countered by the significant challenges associated with fabricating 3-D PBG structures. Fabricated 3-D structures reported to date lack the reproducibility and design versatility required for functional devices [41.21].

3-D Lithographic Fabrication Methods

Fabrication of 3-D PCs using top-down micromachining techniques has been more difficult than for 2-D PCs.

Fig. 41.7a,b Examples of 3-D photonic crystal structures: (a) Yablonovite, obtained by drilling holes in a homogeneous dielectric material (15 GHz); and (b) wood-pile structure, obtained by stacking micromachined Si rods (500 GHz) [41.2]

The first experimental demonstration of a full 3-D photonic band gap was performed in the microwave region (i.e., at 15 GHz, $\lambda \approx 2$ cm), due to the relative ease of fabrication of appropriate structures on the centimeter scale [41.58] (Fig. 41.7). Another case of a full PBG was demonstrated at 500 GHz ($\lambda \approx 600 \mu\text{m}$) with a 3-D structure fabricated by assembling micromachined silicon dielectric rods [41.59] (Fig. 41.7) into log-pile structures [41.60, 61].

In a 3-D lattice, theoretical calculations have determined that the band gap position is generally about one half to one third of the periodicity scale [41.62]. This translates into patterning the dielectric materials with features of 100–300 nm in all three dimensions, with required alignment accuracies among the different layers exceeding tens of nanometers [41.62]. In addition, with air as the second dielectric, the empty volume required for large PBGs is so large (≈ 70 –80%) that the mechanical stability of the structure becomes very poor, adding another challenge for the etching procedure [41.2]. Often 3-D PC structures are so full of defects after such etching that the systems no longer exhibit significant PC behavior [41.2].

Due to difficulties in fabricating structures in the optical or near-infrared frequencies [41.2, 62, 63], only a few experimental systems have recently demonstrated the signature of a complete PBG. Lithographically derived 3-D structures require many complex fabrication steps, and it takes many months to make a single structure. Some examples of prototype 3-D PC include log-pile structures fabricated using layer-by-layer patterning (i.e., repeated deposition and etching) of Si [41.64] (Fig. 41.8), and structures fabricated using wafer fusion combined with etching in GaAs and InP [41.65] (Fig. 41.8). In the former case, processing difficulties have limited the number of layers in such 3-D periodic structures (i.e., to below 10) and in the latter cases, to materials other than those commonly used in microelectronics [41.62]. Sequential deposition of dielectric films on a patterned substrate may be used to produce 3-D periodic structures in the *auto-cloning* process [41.66], which is considered to be a relatively cheap and flexible process. However, the range of structures that can be produced with this technique is limited. Also, the technique does not allow the component dielectrics to be continuously connected in 3-D [41.67].

Hole-drilling has also been implemented using X-ray lithography [41.68] and can be scaled to optical frequencies by directional etching through a mask on a semiconductor surface [41.69]. Other

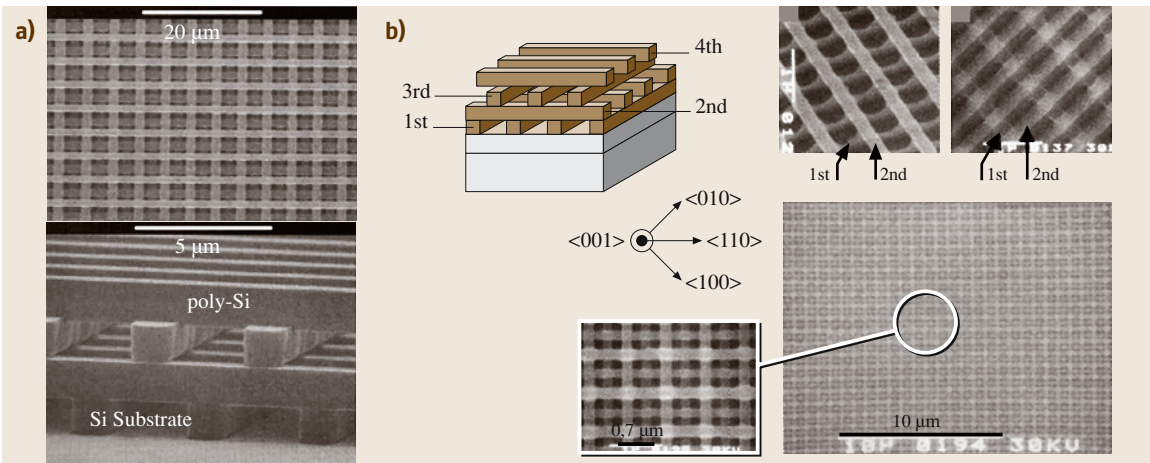

Fig. 41.8a,b Examples of 3-D PBG structures fabricated by micromachining/lithographic techniques: (a) advanced lithography [41.64], (b) wafer fusion [41.65]

fabrication methods include direct laser writing, but its resolution is currently only suitable for infrared structures.

3-D Self-Assembly Methods: Inverse Opals

The technological challenges involved in extending microlithographic techniques to 3-D patterning have made self-assembly methods attractive for 3-D PC fabrication. The benefits of using this type of bottom-up assembly for 3-D fabrication include its low capital cost, and its parallel and rapid nature, which allows the ordered fabrication of 3-D PBG-type structures over macroscopic length scales [41.3, 62, 73, 74]. However, self-assembly methods for 3-D PC fabrication are often material-specific, and templated bottom-up PCs tend to have diluted properties compared to bulk single crystals, typically containing unintentional defects and lacking reproducibility.

Self-organized 3-D colloidal crystal structures in a face-centered-cubic lattice (i.e., artificial opals) can be fabricated through sedimentation of colloidal suspensions (i.e., typically spheres, but other structures, such as micelles formed from rod-coil block copolymers have been used). Previously, colloidal crystals were not considered appropriate for PCs with band gaps in the visible and IR ranges because the colloids [typically SiO₂ or polymer materials such as polystyrene (PS) [41.75, 76]

Fig. 41.9a–c Examples of 3-D inverse opal PBG structures: (a) graphite (using CVD infiltration) [41.70], (b) Si (using CVD infiltration) [41.71], (c) titania (using liquid-phase chemical reaction) [41.72]

or poly (methyl-methacrylate) (PMMA)] have refractive indices ≈ 1.5 , which are too low to obtain a full PBG [41.77–79]. Such structures have weak refractive-index contrast, but theoretical calculations have shown that the final porosity of the artificial opal is too small to ever obtain a full PBG, even with very high refractive-index contrast [41.1, 3, 73].

These colloidal structures may also be infiltrated with a second material of higher refractive index to potentially improve the dielectric contrast [41.77, 80], while providing the required dimensional control and low solid fraction [41.74]. So called *inverse* structures can be formed when the original colloidal structure is removed to leave a macroporous structure. Calculations have shown that these inverse structures give rise to larger PBGs for the same refractive-index contrast [41.81]. The porous materials obtained using this approach have also been referred to as *inverse opals* or *inverted opals* because they have an open, periodic 3-D framework complementary to that of the parent opal. Modeling suggests that a porous material consisting of an opaline lattice of interconnected air balls (embedded in an interconnected matrix with a higher refractive index) should produce a full PBG. Optimum photonic effects require that the volume fraction of the matrix material should be 20–30%. Template-based synthesis based on colloids is attractive because the periodicity of this system can be conveniently tuned and a wide variety of materials with relatively high refractive index can be used [41.73]. There have been many examples of inverse opals using materials such as carbon, titania, zirconia, Si and Ge reported in the literature [41.3, 70–74, 82–89] (Fig. 41.9).

The inverse structure is made by infiltrating the interstitial void spaces ($\approx 26\%$ by volume) between the colloidal spheres in the opaline array with a fluid precursor. The fluid may be a pure liquid (e.g., a liquid metal alkoxide or a molten metal), a solution (e.g., a salt solution), a vapor (e.g., using CVD), or a colloidal dispersion of nanocrystals (e.g., colloidal gold particles) [41.73, 74]. Alternately, suspensions containing nanoparticle precursors (with sizes of ≈ 1 –50 nm) and monodisperse spheres can be co-precipitated into an ordered structure [41.73, 74]. The void spaces between the colloidal spheres has also been filled using a variety of materials by electrochemical deposition [41.73]. The fidelity of this procedure is mainly determined by van der Waals interactions, the wetting of the template surface, kinetic factors such as the filling of the void spaces in the template, and the volume shrinkage of precursors during solidification [41.73].

The choice of wall material depends on the desired optical functionality of the PC, as its properties depend on the transparency region of the dielectric material. The availability of a precursor that can infiltrate the voids between the colloidal spheres without significantly swelling or dissolving the template is critical. For example, high-temperature infiltration techniques exclude the use of polymer templates. The precursor must be carefully chosen to allow for shrinkage occurring during solidification and the final grain size, which affects the smoothness, density, effective refractive index, PC wall structure and the mechanical properties of the final 3-D PC [41.74]. The approach and conditions used for infiltration can affect the filling efficiencies (i.e., the effective wall density) which, in turn, affect the mechanical strength and reduces the average refractive index of the walls [41.74, 82]. Choice of template also depends on the method of solidification of the precursor and whether the template can be selectively removed from the wall material, either chemically or by heating during the final fabrication step.

Porous structures are produced by the removal of the colloidal templates, either by burning, extracting with a solvent, or, in the case of silica colloids, by dissolving with dilute hydrofluoric (HF) acid. The method of template removal depends on the colloid material and on the properties of the infiltrated precursor. Silica sphere template arrays are removed by dissolution in aqueous HF solutions [41.74, 88]. Most metal-oxide inverse opals have typically been synthesized using polymer spheres as templates [41.74]. Polymer sphere template arrays are often removed thermally, with the added benefit of chemically converting the sol-gel precursors in the infiltrated phase to the desired oxide product [41.74, 88]. If precursor solidification is feasible at low temperatures, or if the precursor has components that would be destroyed by thermal template removal, polymer spheres can also be removed chemically using organic solvents, such as toluene, or tetrahydrofuran (THF) and acetone mixtures, or by photodegradation [41.74, 88].

Fabrication of such structures is not trivial: some of the difficulties include incomplete infiltration, structural shrinkage after infiltration, and microstructural variations (affecting the refractive index). A major problem with chemical assembly is that residual disorder drastically reduces the PBG width and the intensity of the reflectance peaks [41.74, 85]. Such disorder can arise from several different sources. Firstly, there are defects in the initial opal template, such as stacking faults or small deviations in sphere size or shape. It is not clear whether the imperfections present in current in-

verse opals are small enough to observe a complete PBG [41.3]. While progress has been made in reducing such defects, numerical simulations predict that even a 2% deviation in sphere size (or lattice constant) can close a PBG in even high-refractive-index inverted opals [41.3, 74]. Secondly, significant disorder can arise from the infiltration process itself. Even the best samples to date have variations in the amount of guest material filling the lattice [41.3]. Since these inhomogeneities must be much smaller than the optical wavelength, the elimination of residual order remains a challenge with such methods [41.3].

Although 3-D inverse opals are fascinating research objects, they are not amenable for practical photonic applications because of difficulties in integrating them into PLCs. Thus, there is strong interest in fabricating 3-D inverse opals in pseudo-2-D form, or supported on a substrate as an inverse opal film, to be compatible with traditional optoelectronic elements for system integration [41.1, 86, 91–93]. Recently, ordered colloidal crystal films have been formed by convective assembly [41.86] by particle confinement in thin slits between two solid plate boundaries [41.73, 86] and by compacting particles in the dry state [41.86, 91, 93–96]. Recently, patterned substrates were successfully used to control slow sedimentation of colloidal particles to improve the long-range order and to induce growth along a specific crystal plane [41.74, 86]. However, growth of defect-free crystalline templates with desired symmetry and orientation remains one of the challenges of the field.

Liquid sol–gel precursors can be used to form a variety of oxide materials and are very convenient for infiltration into artificial opal templates [41.88, 97]. However, the typical high percentage of volume shrinkage (typically 15–30%) involved in the solidification of such sol–gel precursors during the precursor-to-oxide conversion process has often resulted in random cracks in the final inverse opal films [41.73, 74, 88], often preventing the fabrication of large, ordered, inverse opal film structures. Colloidal template films have been infiltrated by soaking the template into the precursor sol–gel solution [41.74, 85, 98], but achieving a dense, complete filling of the void spaces within the 3-D template film has proven to be challenging [41.97]. Another approach used for large-area inverse opal film fabrication involves the crystallization of colloids in a liquid medium containing nanoparticles of the desired material, which are subsequently packed into a dense, 3-D lattice [41.74, 97]. The main limitation of this method is that nanometer-sized particles are not always available for the desired wall ma-

Fig. 41.10a,b Scanning electron microscope images [41.90] of Pb-doped BST inverse opal thin film: (a) cross section; and (b) top view

terial, and so only very specific materials may be made into inverse opals [41.88]. Another method of fabricating high-quality inverse opal films derived from liquid precursors is by infiltrating a sol–gel liquid precursor into a colloidal crystal template film by spin-coating, which results in very uniform filling of the template [41.90] (Fig. 41.10). By comparison, solvent-extracted samples shrink about 10% less [41.88]. Thus, for organic polymers, it has been possible to fabricate such 3-D porous structures as free-standing thin films that are several square centimeters in area.

Alternative 3-D PBG Fabrication Methods

Alternative approaches to lithography or self-assembly for 3-D fabrication exist. Some notable examples include laser-guided stereolithography, in which structures can also be written directly layer-by-layer by using a tightly focused laser beam to cause chemical vapor deposition [41.99], and two-photon-induced deposition or polymerization [41.100, 101]. Currently, feature sizes that can be routinely achieved using these methods are

on the order of a few micrometers due to focusing and diffraction effects.

A 3-D holographic patterning process using multiple laser beams has recently been investigated; a 3-D laser interference pattern exposes a photosensitive polymer precursor (i. e., a photoresist) rendering the exposed areas insoluble and unexposed areas are dissolved away

to leave a 3-D PC formed of cross-linked polymer with air-filled voids [41.102]. This process allows flexible design of the structure of a unit cell and thus of the optical properties of the microstructured material. Of concern is that such structures have relatively weak refractive-index contrast, and the processing approach is quite demanding [41.62].

41.3 Tunable PCs

Although conventional PCs offer an ability to control light propagation or confinement through the introduction of defects, once such defects are introduced, the propagation or confinement of light in these structures is not controllable. Thus, discretionary switching of light, for example, or rerouting of optical signals, is not available with fixed defects in PCs. There are two approaches that have been pursued to tune the properties of PCs: these are by tuning the refractive index of the constituent materials, or by altering the physical structure of the PC. In the latter case, the emphasis has been principally on changing the lattice constant, although other approaches are also relevant (i. e., including for example, the fill factor, structure symmetry and scattering element shape). In the text below, we discuss the state of the art in both of these areas.

41.3.1 Tuning the PC Response by Changing the Refractive Index of the Constituent Materials

We discuss recent progress in using four approaches within this category – namely, tuning the PC response by using: (i) light, (ii) applied electric fields, (iii) temperature or electrical field in infiltrated PCs, and (iv) by changing the concentration of free carriers (using electric field or temperature) in semiconductor-based PCs.

PC Refractive-Index Tuning Using Light

One approach to modifying the behavior of PCs is to use intense illumination of the PC by one beam of light to change the optical properties of the crystal in a nonlinear fashion; this, in turn, can thus control the properties of the PC for another beam of light. An example of a nonlinear effect includes the flattening of the photon dispersion relation near a PBG, which relaxes the constraints on phase matching for second- and third-harmonic generation [41.103]. In addition, light location near defects can enhance a variety of third-order nonlinear processes in 1-D PCs [41.104].

A new approach for PBG tuning has been proposed based on photo-reversible control over molecular aggregation, based on using the photochromic effect in dyes [41.105]. This can cause a reversible change over the photonic stop band. Structures that were studied included opal films formed from 275-nm-diameter silica spheres, infiltrated with photochromic dye: two dyes were considered – namely, 1,3-dihydro-1,3,3-trimethylspiro-[2H-indol-2,3'-[3H]-naphth[2,1-b] [1,4]oxazine] (SP) and cis-1,2-dicyano-1,2-bis(2,4,5-trimethyl-3-trienyl)ethane (CMTE). For the SP dye opal, a reversible 15-nm shift in the reflectance spectrum was observed following UV irradiation, which was ascribed to changes in the reflective index due to resonant absorption near the stop band. Smaller shifts (of about 3 nm) were observed for the CMTE dye opal. The recovery process on cessation of UV illumination was quite slow, taking about 38 s for the SP dye.

Nonlinear changes in refractive index have also been studied in PCs consisting of 220-nm-diameter SA (self assembly) polystyrene spheres infiltrated with water [41.106]. In these studies, the optical Kerr effect was used to shift the PBG. 40 GW/cm² [41.2] of peak pump power at 1.06 μ m (35-ps pulses at 10-Hz repetition rate) was used to shift the PBG 13 nm. The large optical nonlinearity originates from the delocalization of conjugated π -electrons along the polymer chains, leading to a large third-order nonlinear optical susceptibility. The time response was measured as a function of the delay time between pump and probe, and confirmed a response time of several picoseconds.

PC Refractive-Index Tuning Using an Applied Electric Field

There have been a number of studies focusing on using ferroelectric materials to form PCs [41.90, 98, 107, 108]. The application of an electric field to such materials can be used to change the refractive index and tune the PC optical response. For example, lead lanthanum zirconate titanate (PLZT) inverse opal structures have been fabri-

cated by infiltration using 350-nm-diameter polystyrene sphere templates and annealing at 750 °C [41.107]. The films were formed on indium tin oxide (ITO) coated glass to enable electric-field-induced changes in reflectivity to be measured due to the electro-optic effect. Applying voltages of up to about 700 V across films of thickness of about 50 nm only achieved a few nm of peak shift, attributed to the very modest changes in refractive index from the applied field (i.e., from 2.405 to 2.435, as a result of the bias). It should be noted, however, that the intrinsic response of the electro-optic effect in these materials is known to be in the GHz range and hence highly suitable for rapid tuning. Other reports include the formation of inverse opal barium strontium titanate (BST) PCs using infiltration of polystyrene opals [41.90, 98]. BST is most interesting in that it provides a high-refractive-index material and a factor of at least two times higher breakdown field strength than PLZT, and hence offers a much wider range of applied fields for tuning. Reports of using other ferroelectric materials include a high-temperature infiltration process for the ferroelectric copolymer, poly(vinylidene fluoride-trifluoroethane), infiltrated into 3-D silica opals with sphere diameters of 180, 225 and 300 nm [41.108].

Refractive-Index Tuning of Infiltrated PCs

In this case the approach has been to consider modulation of the refractive index of a PC infiltrated with a tunable medium – in particular, the most popular approach has been to use liquid crystals to infiltrate porous 2-D and 3-D PC structures. Such liquid crystals can behave as ferroelectrics whose refractive index may be tuned using either an applied electric field, or by thermal tuning. Reported results for this approach, using 3-D inverse opal structures, have been restricted to infiltration of ferroelectric liquid-crystal material into a silicon/air PC [41.109]. Reported changes in the refractive index of the liquid crystal are 1.4–1.6 under an applied field [41.109]. However, since the ferroelectric liquid has a higher refractive index than air, the infiltration results in a significant decrease in the refractive index contrast. This means that the original full photonic band gap of the inverse opal silicon PC no longer exists, and the practical utility of the silicon structure as a PC is effectively lost. Theoretical simulations have shown that partial surface wetting of the internal inverse opal surface can retain the full photonic band in silicon [41.109], but it is questionable whether such a complex structure can ever be practically fabricated. Finally, the presence of ferroelectric liquid crystal surrenders one of the main advantages of the original concept for PC structures: that

is, permitting light propagation in air [41.110]. Temperature tuning of the liquid-crystal material was shown to result in very small changes in refractive index (changes in $n < 0.01$ over a 70 °C change) and thus only provide minimal shifts in the transmittance through the PC over a large temperature range [41.111].

PC Refractive-Index Tuning by Altering the Concentration of Free Carriers (Using Electric Field or Temperature) in Semiconductor-Based PCs

An elegant way to rapidly tune the PBG of semiconductor-based PCs is to adjust the refractive index by modulating the free-carrier concentration using an ultra-fast optical pulse [41.112]. Using this approach, reflectivity of a two-dimensional silicon-based honeycomb PCs with 412-nm air holes (100 μm in length) in a 500-nm periodic array, was studied with a pump–probe approach [41.112]. By varying the delay between the pump the speed of PBG tuning was measured to be about 0.5 ps. The reflectance relaxation (corresponding to the return of the PBG to its original position) occurred on a timescale of 10–100 ns, characteristic of recombination of excess electrons and holes. Although these results are very encouraging, this approach cannot suppress or correct for light-scattering losses caused by structural imperfections, which remain an important consideration for currently fabricated PCs.

4.1.3.2 Tuning PC Response by Altering the Physical Structure of the PC

The second approach that we discuss for tuning the response of a PC is based on changes to the physical structure of the PC. We discuss the following approaches for tuning using this approach: tuning using (i) temperature, (ii) an applied magnetic field, (iii) strain/deformation, (iv) piezoelectric effects, and (v) using micro-electro-mechanical systems (MEMS) [i.e., actuation].

Tuning PC Response Using Temperature

An example of this approach is a study of temperature tuning of PCs fabricated from self-assembled polystyrene beads [41.113]. The PBG in these structures was fine-tuned by annealing samples at temperatures of 20–100 °C, resulting in a continuous blue shift of the stop band wavelength from 576 nm to 548 nm. New stop bands appeared in the UV transmission spectra when the sample was annealed above about 93 °C – the glass-transition temperature of the polystyrene beads.

Tuning PC Response Using Magnetism

An example of this approach is the use of an external applied magnetic field to adjust the spatial orientation of a PC [41.97]. This can find application in fabricating photonic devices such as tunable mirrors and diffractive display devices. These authors fabricated magnetic PCs by using monodisperse polystyrene beads self-assembled into a ferro-fluid consisting of magnetite particles, with particle sizes below 15 nm [41.97]. On evaporation of the solvent, a cubic PC lattice was formed with the nanoparticles precipitating out into the interstices between the spherical polystyrene colloids. These authors then showed how the template could be selectively removed by calcination or wet etching to reveal an inverse opal of magnetite – such structures being proposed as suitable for developing magnetically tunable PCs.

Tuning PC Response Using Strain

The concept in this case is quite straightforward – deforming or straining the PC changes the lattice constant or arrangement of dielectric elements in the PC with concomitant change in the photonic band structure. Polymeric materials would appear to be most suited to this methodology, owing to their ability to sustain considerable strains. However, concerns of reversibility and speed of tuning would clearly need to be addressed. Theoretical predictions for the influence of deformation on such systems include a report on a new class of PC based on self-assembling cholesteric elastomers [41.114]. These elastomers are highly deformable when subjected to external stress. The high sensitivity of the photonic band structure to strain, and the opening of new PBGs have been discussed [41.114]. Charged colloidal crystals were also fixed in a poly(acrylamide) hydrogel matrix to fabricate PCs whose diffraction peaks were tuned by applying mechanical stress [41.115]. The PBG shifted linearly and reversibly over almost the entire visible spectral region (from 460 nm to 810 nm).

Modeling of the photonic band structure of 2-D silicon-based triangular PCs under mechanical deformation was also reported [41.116]. The structures considered consisted of a silicon matrix with air columns. The authors showed that while a 3% applied shear strain provides only minor modifications to the PBG, uniaxial tension can produce a considerable shift. Other modeling includes a study of how strain can be used to tune the anisotropic optical response of 2-D PCs in the long-wavelength limit [41.117]. These calculations showed that the decrease in dielectric constant per unit strain is larger in the direction of the strain

than normal to it. Indeed, the calculated birefringence is larger than that of quartz. They suggest that strain-tuning of this birefringence has attractive application in polarization-based optical devices.

To appreciate the sensitivity of such structures to mechanical tuning, it is instructive to refer to some recent work on PMMA inverse opal PC structures that were fabricated using silica opal templates [41.118]. Under the application of uniaxial deformation of these PCs, the authors found a blue shift of the stop band in the transmission spectrum – the peak wavelength of the stop band shifted from about 545 nm in the undeformed material to about 470 nm under a stretch ratio of about 1.6.

Another practical approach that has been applied to physically tuning PC structures is that of thermal annealing. One such study showed how the optical properties of colloidal PCs consisting of silica spheres can be tuned through thermal treatment [41.119]. This was attributed to both structural and physio-chemical modification of the material on annealing. A shift in the minimum transmission from about 1000 nm (un-annealed) to about 850 nm (for annealing at about 1000 °C) was demonstrated, or about a maximum shift in Bragg wavelength of $\approx 11\%$.

A quite novel application of strain-tuning was recently reported [41.120]. The authors studied 2-D PCs consisting of arrays of coupled optical microcavities fabricated from vertical-cavity surface-emitting laser structures. The influence of strain, as manifested by shifts in the positions of neighboring rows of microcavities with respect to each other, corresponded to alternating square or quasi-hexagonal shear-strain patterns. For strains below a critical threshold value, the lasing photon mode-locked to the corresponding mode in the unstrained PC. At the critical strain, switching occurred between the square and hexagonal lattice modes.

Finally, there has been a proposal for using strain in a PC to tune the splitting of a degenerate photon state within the PBG, suitable for implementing tunable PC circuits [41.121]. The principle applied is analogous to the static Jahn–Teller effect in solids. These authors showed that this effect is tunable by using the symmetry and magnitude of the lattice distortion. Using this effect the design of an optical valve that controls the resonant coupling of photon modes at the corner of a T-junction waveguide structure has been discussed.

Tuning PC Response Using Piezoelectric Effects

In this section we discuss using piezoelectric effects to physically change PC structures and hence tune them.

A proposal was made for using the piezoelectric effect to distort the original symmetry of a two-dimensional PC from a regular hexagonal lattice to a quasi-hexagonal lattice under an applied electric field [41.122]. The original bands decomposed into several strained bands, dependent on the magnitude and direction of the applied field. In the proposed structures, the application of $\approx 3\%$ shear strain is shown to be suitable for shifting 73% of the original PBG, which they refer to as the tunable-band-gap regime. An advantage of such an approach is that such structures are suggested to be capable of operation at speeds approaching MHz. Another report [41.123] discusses the design and implementation of a tunable silicon-based PBG microcavity in an optical waveguide, where tuning is accomplished using the piezoelectric effect to strain the PC; this was carried out using integrated piezoelectric microactuators. These authors report on a 1.54-nm shift in the cavity resonance at 1.56 μm for an applied strain of 0.04%.

There have also been reports of coupling piezoelectric-based actuators to PCs. One such report [41.124] discusses a poly(2-methoxyethyl acrylate)-based PC composite directly coupled to a piezoelectric actuator to study static and dynamic stop-band tuning characteristics; the stop band of this device could be tuned through a 172-nm tuning range, and could be modulated at up to 200 Hz.

Tuning PC Response Using Micro-Electro-Mechanical Systems (MEMS) Actuation

There have been a number of interesting developments in this field including PC-based air-bridge devices consisting of suspended 1-D PC mirrors separated by a Fabry–Perot cavity (gap) [41.125]. When such structures are mechanically perturbed, there can be a substantial shift in the PBG due to strain. The au-

thors discuss how a suite of spectrally tunable devices can be envisioned based on such structures – these include modulators, optical filters, optical switches, WDM (wavelength division multiplexing), optical logical circuits, variable attenuators, power splitters and isolators. Indeed, the generalization of these concepts beyond 1-D was discussed in a recent patent [41.126] that covers tunable PC structures. This report [41.126], as well as others [41.127], consider the extension of these ideas to form families of micromachined devices. These authors [41.127] modeled and implemented a set of micromachined vertical resonator structures for 1.55- μm filters consisting of two PC (distributed Bragg reflector [DBR]) mirrors separated by either an air gap or semiconductor heterostructure. Electro-mechanical tuning was used to adjust the separation between the mirrors and hence fine-tune the transmission spectrum. The mirror structures were implemented using strong-index-contrast InP/air DBRs giving an index contrast of 2.17, and weak-index-contrast (0.5) silicon nitride/silicon dioxide DBRs. In the former case, a tuning range of over 8% of the absolute wavelength was achieved; varying the inter-membrane voltage up to 5 V gave a tuning range of over 110 nm. Similar planar structures are discussed in other papers [41.128] where the mirrors are formed from two slabs of PC separated by an adjustable air gap [41.126]. These structures have been shown to be able to perform as either flat-top reflection or all-pass transmission filters, by varying the distance between the slabs, for normally incident light. Unlike all previously reported all-pass reflection filters, based on Gires–Tournois interferometers using multiple dielectric stacks, their structure generates an all-pass transmission spectrum, significantly simplifying signal extraction and optical alignment – also the spectral response is polarization-independent owing to the 90° rotational symmetry of their structure.

41.4 Summary and Conclusions

This chapter discussed the fabrication and properties of PCs, with emphasis on developing tunable structures. New fabrication methodologies and also tuning schemes offers a glimpse of the far-reaching prospects for developing photonic devices which can, in a discretionary fashion, control the propagation of modes of light in an

analogous fashion to the way in which nanostructures have been harnessed to control electron-based phenomena. Analogous to the evolution of electronic systems, one can anticipate a path toward development of compact active integrated photonic systems, as envisioned based on the technology outlined in this review.

42. Quantum Wells, Superlattices, and Band-Gap Engineering

This chapter reviews the principles of band-gap engineering and quantum confinement in semiconductors, with a particular emphasis on their optoelectronic properties. The chapter begins with a review of the fundamental principles of band-gap engineering and quantum confinement. It then describes the optical and electronic properties of semiconductor quantum wells and superlattices at a tutorial level, before describing the principal optoelectronic devices. The topics covered include edge-emitting lasers and light-emitting diodes (LEDs), resonant cavity LEDs and vertical-cavity surface-emitting lasers (VCSELs), quantum cascade lasers, quantum-well solar cells, superlattice avalanche photodiodes, inter-sub-band detectors, and quantum-well light modulators. The chapter concludes with a brief review of current research topics, including a discussion of quantum-dot structures.

42.1 Principles of Band-Gap Engineering and Quantum Confinement	1022
42.1.1 Lattice Matching	1022
42.1.2 Quantum-Confined Structures	1023

The need for efficient light-emitting diodes and lasers operating over the whole of the visible spectrum and also the fibre-optic windows at 1.3 μm and 1.55 μm drives research into new direct-gap semiconductors to act as the active materials. Since the emission wavelength of a semiconductor corresponds to its band-gap energy, research focuses on engineering new materials which have their band gaps at custom-designed energies. This science is called *band-gap engineering*.

In the early years of semiconductor optoelectronics, the band gaps that could be achieved were largely determined by the physical properties of key III–V materials such as GaAs and its alloys such as AlGaAs and InGaAs. Then in 1970 a major breakthrough occurred when *Esaki* and *Tsu* invented the semiconductor quantum well and superlattice [42.1]. They realised that developments in epitaxial crystal growth could open the door to new

structures that exploit the principles of quantum confinement to engineer electronic states with custom-designed properties. They foresaw that these quantum-confined structures would be of interest both to research scientists, who would be able to explore uncharted areas of fundamental physics, and also to engineers, who would learn to use their unique properties for device applications. Their insight paved the way for a whole new breed of devices that are now routinely found in a host of everyday applications ranging from compact-disc players to traffic lights.

The emphasis of the chapter is on the optoelectronic properties of quantum-well and superlattice structures. We begin by outlining the basic principles of band-gap engineering and quantum confinement. We will then discuss the electronic states in quantum-confined structures and the optical properties that follow from

them. In Sects. 42.3–42.5 we will explain the principles of the main optoelectronic devices that employ quantum wells and superlattices, namely emitters, detectors and modulators. Finally we will indicate a few interesting recent developments that offer exciting prospects for future devices before drawing the chapter to its

conclusion. A number of texts cover these topics in more detail (e.g. [42.2–5]), and the interested reader is referred to these sources for a more comprehensive treatment. A description of the purely electronic properties of low-dimensional structures may be found in [42.6].

42.1 Principles of Band-Gap Engineering and Quantum Confinement

42.1.1 Lattice Matching

The art of band-gap engineering relies heavily on developments in the science of crystal growth. Bulk crystals grown from the melt usually contain a large number of impurities and defects, and optoelectronic devices are therefore grown by epitaxial methods such as liquid-phase epitaxy (LPE), molecular-beam epitaxy (MBE) and metalorganic vapour-phase epitaxy (MOVPE), which is also called metalorganic chemical vapour deposition (MOCVD) (Chapt. 14). The basic principle of epitaxy is to grow thin layers of very high purity on top of a bulk crystal called the substrate. The system is said to be *lattice-matched* when the lattice constants of the epitaxial layer and the substrate are identical. Lattice-matching reduces the number of dislocations in the epitaxial layer, but it also imposes tight restrictions on the band gaps that can be engineered easily, because there are only a relatively small number of convenient substrate materials available.

Fig. 42.1 Room-temperature band gap of a number of important optoelectronic III–V materials versus their lattice constant

We can understand this point more clearly by reference to Fig. 42.1. This diagram plots the band-gap energy E_g of a number of important III–V semiconductors as a function of their lattice constant. The majority of optoelectronic devices for the red/near-infrared spectral regions are either grown on GaAs or InP substrates. The simplest case to consider is an epitaxial layer of GaAs grown on a GaAs substrate, which gives an emission wavelength of 873 nm (1.42 eV). This wavelength is perfectly acceptable for applications involving short-range transmission down optical fibres. However, for long distances we require emission at 1.3 μm or 1.55 μm , while for many other applications we require emission in the visible spectral region.

Let us first consider the preferred fibre-optic wavelengths of 1.3 μm and 1.55 μm . There are no binary semiconductors with band gaps at these wavelengths, and so we have to use alloys to tune the band gap by varying the composition (Chapt. 31). A typical example is the ternary alloy $\text{Ga}_x\text{In}_{1-x}\text{As}$, which is lattice-matched to InP when $x = 47\%$, giving a band gap of 0.75 eV (1.65 μm). $\text{Ga}_{0.47}\text{In}_{0.53}\text{As}$ photodiodes grown on InP substrates make excellent detectors for 1.55- μm radiation, but to make an emitter at this wavelength, we have to increase the band gap while maintaining the lattice-matching condition. This is achieved by incorporating a fourth element into the alloy – typically Al or P, which gives an extra design parameter that permits band-gap tuning while maintaining lattice-matching. Thus the quaternary alloys $\text{Ga}_{0.27}\text{In}_{0.73}\text{As}_{0.58}\text{P}_{0.42}$ and $\text{Ga}_{0.40}\text{In}_{0.60}\text{As}_{0.85}\text{P}_{0.18}$ give emission at 1.3 μm and 1.55 μm , respectively, and are both lattice-matched to InP substrates.

Turning now to the visible spectral region, it is a convenient coincidence that the lattice constants of GaAs and AlAs are almost identical. This means that we can grow relatively thick layers of $\text{Al}_x\text{Ga}_{1-x}\text{As}$ on GaAs substrates without introducing dislocations and other defects. The band gap of $\text{Al}_x\text{Ga}_{1-x}\text{As}$ varies quadratically

with x according to:

$$E_g(x) = (1.42 + 1.087x + 0.438x^2) \text{ eV}, \quad (42.1)$$

but unfortunately the gap becomes indirect for $x > 43\%$. We can therefore engineer direct band gaps of 1.42–1.97 eV, giving emission from 873 nm in the near infrared to 630 nm in the red spectral range. Much work has been done on quaternary alloys such as AlGaInP, (Chapt. 31) but it has not been possible to make blue- and green-emitting devices based on GaAs substrates to date, due to the tendency for arsenic and phosphorous compounds to become indirect as the band gap increases.

The approach for the blue end of the spectrum preferred at present is to use nitride-based compounds. (Chapt. 32) Early work on nitrides established that their large direct gaps made them highly promising candidates for use as blue/green emitters [42.7]. However, it was not until the 1990s that this potential was fully realised. The rapid progress followed two key developments, namely the activation of p-type dopants and the successful growth of strained $\text{In}_x\text{Ga}_{1-x}\text{N}$ quantum wells which did not satisfy the lattice-matching condition [42.8]. The second point goes against the conventional wisdom of band-gap engineering and highlights the extra degrees of freedom afforded by quantum-confined structures, as will now be discussed.

42.1.2 Quantum-Confined Structures

A quantum-confined structure is one in which the motion of the electrons (and/or holes) are confined in one or more directions by potential barriers. The general scheme for classifying quantum-confined structures is given in Table 42.1. In this chapter we will be concerned primarily with *quantum wells*, although we will briefly refer to *quantum wires* and *quantum dots* in Sect. 42.6. Quantum size effects become important when the thickness of the layer becomes comparable with the de Broglie wavelength of the electrons or holes.

Table 42.1 Classification of quantum-confined structures. In the case of quantum wells, the confinement direction is usually taken as the z -axis

Structure	Confined directions	Free directions (dimensionality)
Quantum well	1 (z)	2 (x, y)
Quantum wire	2	1
Quantum dot (or box)	3	none

If we consider the free thermal motion of a particle of mass m in the z -direction, the de Broglie wavelength at a temperature T is given by

$$\lambda_{\text{deB}} = \frac{h}{\sqrt{mk_B T}}. \quad (42.2)$$

For an electron in GaAs with an effective mass of $0.067m_0$, we find $\lambda_{\text{deB}} = 42 \text{ nm}$ at 300 K. This implies that we need structures of thickness $\approx 10 \text{ nm}$ in order to observe quantum-confinement effects at room temperature. Layers of this thickness are routinely grown by the MBE or MOVPE techniques described in Chapt. 14.

Figure 42.2 shows a schematic diagram of a GaAs/AlGaAs quantum well. The quantum confinement is provided by the discontinuity in the band gap at the interfaces, which leads to a spatial variation of the conduction and valence bands, as shown in the lower half of the figure. The Al concentration is typically chosen to be around 30%, which gives a band-gap discontinuity of 0.36 eV according to (42.1). This splits roughly 2 : 1 between the conduction and valence bands, so that electrons see a confining barrier of 0.24 eV and the holes see 0.12 eV.

If the GaAs layers are thin enough, according to the criterion given above, the motion of the electrons and holes will be quantised in the growth (z) direction, giving

Fig. 42.2 Schematic diagram of the growth layers and resulting band diagram for a GaAs/AlGaAs quantum well of thickness d . The quantised levels in the quantum well are indicated by the *dashed lines*. Note that in real structures a GaAs buffer layer is usually grown immediately above the GaAs substrate

rise to a series of discrete energy levels, as indicated by the dashed lines inside the quantum well in Fig. 42.2. The motion is in the other two directions (i.e. the x - y plane) is still free, and so we have quasi two-dimensional (2-D) behaviour.

The quantisation of the motion in the z -direction has three main consequences. Firstly, the quantisation energy shifts the effective band edge to higher energy, which provides an extra degree of freedom in the art of band-gap engineering. Secondly, the confinement keeps the electrons and holes closer together and hence increases the radiative recombination probability. Finally, the density of states becomes independent of energy, in contrast to three-dimensional (3-D) materials, where the density of states is proportional to $E^{1/2}$. Many of the useful properties of the quantum wells follow from these three properties.

The arrangement of the bands shown in Fig. 42.2 in which both the electrons and holes are confined in the quantum well is called *type I band alignment*. Other types of band alignments are possible in which only one of the carrier types are confined (*type II band alignment*). Furthermore, the flexibility of the MBE and MOVPE growth techniques easily allows the growth of *superlattice* (SL) structures containing many repeated quantum wells with thin barriers separating them, as shown in Fig. 42.3. Superlattices behave like artificial one-dimensional periodic crystals, in which the periodicity is designed into the structure by the repetition of the quantum wells. The electronic states of SLs form delocalised *minibands* as the wave functions in neighbouring wells couple together through the thin barrier that separates them. Structures containing a smaller number of repeated wells or with thick barriers that prevent coupling between adjacent wells are simply called *multiple quantum well* (MQW) structures.

Fig. 42.3 Schematic diagram of a superlattice, showing the formation of minibands from the energy levels of the corresponding single quantum well (QW). The structure forms an artificial one-dimensional crystal with period $(d+b)$, where d and b represent the thickness of the QW and barrier regions respectively. The width of the minibands depends on the strength of the coupling through the barriers. It is frequently the case that the lowest hole states do not couple strongly, and hence remain localised within their respective wells, as shown in the figure

In the next section we will describe in more detail the electronic properties of quantum wells and superlattices. Before doing so, it is worth highlighting two practical considerations that are important additional factors that contribute to their usefulness. The first is that band-gap tunability can be achieved without using alloys as the active material, which is desirable because alloys inevitably contain more defects than simple compounds such as GaAs. The second factor is that the quantum wells can be grown as strained layers on top of a lattice with a different cell constant. A typical example is the $\text{In}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ quantum wells mentioned above. These layers do not satisfy the lattice-matching condition, but as long as the total $\text{In}_x\text{Ga}_{1-x}\text{N}$ thickness is less than the critical value, there is an energy barrier to the formation of dislocations. In practice this allows considerable extra flexibility in the band-gap engineering that can be achieved.

42.2 Optoelectronic Properties of Quantum-Confined Structures

42.2.1 Electronic States in Quantum Wells and Superlattices

Quantum Wells

The electronic states of quantum wells can be understood by solving the Schrödinger equation for the electrons and holes in the potential wells created by the band discontinuities. The simplest approach is the infinite-well model shown in Fig. 42.4a. The Schrödinger equation in

the well is

$$-\frac{\hbar^2}{2m_w^*} \frac{d^2\psi(z)}{dz^2} = E\psi(z), \quad (42.3)$$

where m_w^* is the effective mass in the well and z is the growth direction. Since the potential barriers are infinite, there can be no penetration into the barriers, and we must therefore have $\psi(z) = 0$ at the interfaces. If we choose our origin such that the quantum well runs from $z = 0$

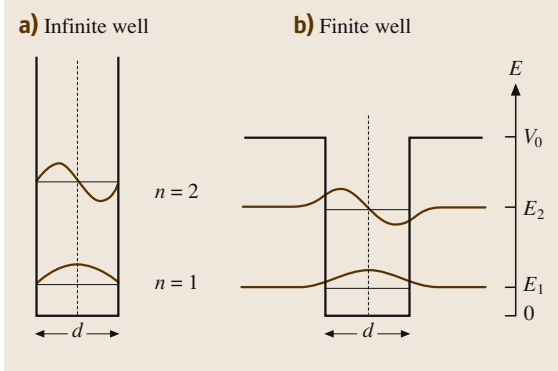

Fig. 42.4a,b Confined states in a quantum well of width d . **(a)** A perfect quantum well with infinite barriers. **(b)** A finite well with barriers of height V_0 . The wave functions for the $n = 1$ and $n = 2$ levels are sketched for both types of well

to $z = d$, d being the width of the well, the normalised wave functions take the form (see e.g. [42.9]):

$$\psi_n(z) = \sqrt{2/d} \sin k_n z, \quad (42.4)$$

where $k_n = (n\pi/d)$ and the quantum number n is an integer (≥ 1). The energy E_n is given by

$$E_n = \frac{\hbar^2 k_n^2}{2m_w^*} = \frac{\hbar^2}{2m_w^*} \left(\frac{n\pi}{d} \right)^2. \quad (42.5)$$

The wave functions of the $n = 1$ and $n = 2$ levels are sketched in Fig. 42.4a.

Although the infinite-well model is very simplified, it nonetheless provides a good starting point for understanding the general effects of quantum confinement. Equation (42.5) shows us that the energy is inversely proportional to d^2 , implying that narrow wells have larger confinement energies. Furthermore, the confinement energy is inversely proportional to the effective mass, which means that lighter particles experience larger effects. This also means that the heavy- and light-hole states have different energies, in contrast to bulk semiconductors in which the two types of hole states are degenerate at the top of the valence band.

Now let us consider the more realistic finite-well model shown in Fig. 42.4b. The Schrödinger equation in the well is unchanged, but in the barrier regions we now have:

$$-\frac{\hbar^2}{2m_b^*} \frac{d^2 \psi(z)}{dz^2} + V_0 \psi(z) = E \psi(z), \quad (42.6)$$

where V_0 is the potential barrier and m_b^* is the effective mass in the barrier. The boundary conditions require that

the wave function and particle flux $(1/m^*)d\psi/dz$ must be continuous at the interface. This gives a series of even and odd parity solutions which satisfy

$$\tan(kd/2) = \frac{m_w^* \kappa}{m_b^* k}, \quad (42.7)$$

and

$$\tan(kd/2) = -\frac{m_b^* k}{m_w^* \kappa}, \quad (42.8)$$

respectively. k is the wave vector in the well, given by

$$\frac{\hbar^2 k^2}{2m_w^*} = E_n, \quad (42.9)$$

while κ is the exponential decay constant in the barrier, given by

$$\frac{\hbar^2 \kappa^2}{2m_b^*} = V_0 - E_n. \quad (42.10)$$

Solutions to (42.7) and (42.8) are easily found by simple numerical techniques [42.9]. As with the infinite well, the eigenstates are labelled by the quantum number n and have parities of $(-1)^{n+1}$ with respect to the axis of symmetry about the centre of the well. The wave functions are approximately sinusoidal inside the well, but decay exponentially in the barriers, as illustrated in Fig. 42.4b. The eigen-energies are smaller than those of the infinite well due to the penetration of the barriers, which means that the wave functions are less well confined. There is only a limited number of solutions, but there is always at least one, no matter how small V_0 might be.

As an example we consider a typical GaAs/Al_{0.3}Ga_{0.7}As quantum well with $d = 10$ nm. The confinement energy is 245 meV for the electrons and 125 meV for the holes. The infinite well model predicts $E_1 = 56$ meV and $E_2 = 224$ meV for the electrons, whereas (42.7), (42.8) give $E_1 = 30$ meV and $E_2 = 113$ meV. For the heavy (light) holes the infinite-well model predicts 11 meV (40 meV) and 44 meV (160 meV) for the first two bound states, instead of the more accurate values of 7 meV (21 meV) and 29 meV (78 meV) calculated from the finite-well model. Note that the separation of the electron levels is greater than $k_B T$ at 300 K, so that the quantisation effects will be readily observable at room temperature.

Strained Quantum Wells

Even more degrees of freedom for tailoring the electronic states can be achieved by epitaxially stacking semiconductor layers with different lattice constants to form *strained quantum wells*. Examples include

$\text{In}_x\text{Ga}_{1-x}\text{As}$ on GaAs, and $\text{Si}_{1-x}\text{Ge}_x$ on Si. Large biaxial strain develops within the x - y plane of a quantum well grown on a substrate with a different lattice constant. In order to avoid the buildup of misfit dislocations at the interfaces, the strained layers need to be thinner than a certain critical dimension. For example, a defect-free strained $\text{In}_x\text{Ga}_{1-x}\text{As}$ layer on GaAs requires a thickness less than around 10 nm when $x = 0.2$. Since the band gap is related to the lattice constant, the strain induces a shift of the band edges which, in turn, affects many other properties. It is due to some of these effects that strained QW structures have become widely exploited in optoelectronic devices. (Chapt. 37)

The most significant effect of the strain is to alter the band gap and remove the valence-band degeneracy near the Γ valley. The splitting of the valence band is a consequence of the lattice distortion, which reduces the crystal symmetry from cubic to tetragonal [42.10]. There are essentially two types of strain. Compressive strain occurs when the active layer has a larger lattice constant than the substrate, for example in $\text{In}_x\text{Ga}_{1-x}\text{As}$ on GaAs. In this case, the band gap increases and the effective mass of the highest hole band decreases, while that of next valence band increases. The opposite case is that of tensile strain, which occurs when the active layer has a smaller lattice constant than the substrate, such as $\text{Si}_{1-x}\text{Ge}_x$ on Si. The ordering of the valence bands is opposite to the case of compressive strain, and the overall band gap is reduced.

Superlattices

The analytical derivation of the allowed energy values in a superlattice (SL) is similar to that for a single QW, with the appropriate change of the boundary conditions imposed by the SL periodicity. The mathematical description of a superlattice is similar to a one-dimensional crystal lattice, which allows us to borrow the formalism of the band theory of solids, including the well-known Kronig-Penney model [42.9]. Within this model, the electron envelope wave function $\psi(z)$ can be expressed as a superposition of Bloch waves propagating along the z -axis. For a SL with a barrier height V_0 , the allowed energy is calculated numerically as a solution of the transcendental equation involving the Bloch wave vector:

$$\begin{aligned} \cos(ka) &= \cos(kd) \cos(\kappa'b) \\ &\quad - \frac{k^2 + \kappa'^2}{2k\kappa'} \sin(kd) \sin(\kappa'b), \\ E &> V_0, \end{aligned} \quad (42.11)$$

$$\begin{aligned} \cos(ka) &= \cos(kd) \cos(\kappa b) \\ &\quad - \frac{k^2 - \kappa^2}{2k\kappa} \sin(kd) \sin(\kappa b), \\ E &< V_0, \end{aligned} \quad (42.12)$$

where $a \equiv (b + d)$ is the period, and k and κ are given by (42.9) and (42.10), respectively. The decay constant κ' is given by:

$$E - V_0 = \frac{\hbar^2 \kappa'^2}{2m_b^*}. \quad (42.13)$$

The electronic states in superlattices can be understood in a more qualitative way by reference to Fig. 42.3 and making use of the analogy with the tight-binding model of band formation in solids. Isolated atoms have discrete energy levels which are localised on the individual atom sites. When the atoms are brought close together, the energy levels broaden into bands, and the overlapping wave functions develop into extended states. In the same way, repeated quantum-well structures with large values of the barrier thickness b (i. e. MQWs) have discrete levels with wave functions localised within the wells. As the barrier thickness is reduced, the wave functions of adjacent wells begin to overlap and the discrete levels broaden into minibands. The wave functions in the minibands are delocalised throughout the whole superlattice. The width of the miniband depends on the cross-well coupling, which is determined by the barrier thickness and the decay constant κ (42.10). In general, the higher-lying states give rise to broader minibands because κ decreases with E_n . Also, the heavy-hole minibands are narrower than the electron minibands, because the cross-well coupling decreases with increasing effective mass.

42.2.2 Interband Optical Transitions

Absorption

The optical transitions in quantum wells take place between electronic states that are confined in the z -direction but free in the x - y plane. The transition rate can be calculated from Fermi's golden rule, which states that the probability for optical transitions from the initial state $|i\rangle$ at energy E_i to the final state $|f\rangle$ at energy E_f is given by:

$$W(i \rightarrow f) = \frac{2\pi}{\hbar} |\langle f | \mathbf{e} \cdot \mathbf{E} | i \rangle|^2 g(\hbar\omega), \quad (42.14)$$

where \mathbf{e} is the electric dipole of the electron, \mathbf{E} is the electric field of the light wave, and $g(\hbar\omega)$ is the joint density of states at photon energy $\hbar\omega$. Conservation of

energy requires that $E_f = (E_i + \hbar\omega)$ for absorption, and $E_f = (E_i - \hbar\omega)$ for emission.

Let us consider a transition from a confined hole state in the valence band with quantum number n to a confined electron state in the conduction band with quantum number n' . We apply Bloch's theorem to write the wave functions in the following form:

$$\begin{aligned} |i\rangle &= u_v(\mathbf{r}) \exp(i\mathbf{k}_{xy} \cdot \mathbf{r}_{xy}) \psi_{hn}(z) \\ |f\rangle &= u_c(\mathbf{r}) \exp(i\mathbf{k}_{xy} \cdot \mathbf{r}_{xy}) \psi_{en'}(z), \end{aligned} \quad (42.15)$$

where $u_v(\mathbf{r})$ and $u_c(\mathbf{r})$ are the envelope function for the valence and conduction bands, respectively, \mathbf{k}_{xy} is the in-plane wave vector for the free motion in the x - y plane, \mathbf{r}_{xy} being the xy component of the position vector, and $\psi_{hn}(z)$ and $\psi_{en'}(z)$ are the wave functions for the confined hole and electron states in the z -direction. We have applied conservation of momentum here so that the in-plane wave vectors of the electron and hole are the same.

On inserting these wave functions into (42.14) we find that the transition rate is proportional to both the square of the overlap of the wave functions and the joint density of states [42.11]:

$$W \propto |\langle \psi_{en'}(z) | \psi_{hn}(z) \rangle|^2 g(\hbar\omega). \quad (42.16)$$

The wave functions of infinite wells are orthogonal unless $n = n'$, which gives a selection rule of $\Delta n = 0$. For finite wells, the $\Delta n = 0$ selection rule is only approximately obeyed, although transitions between states of different parity (i. e. Δn odd) are strictly forbidden. The joint density of states is independent of energy due to the quasi-2-D nature of the quantum well.

Figure 42.5a illustrates the first two strong transitions in a typical quantum well. These are the $\Delta n = 0$ transitions between the first and second hole and electron levels. The threshold energy for these transitions is equal to

$$\hbar\omega = E_g + E_{hn} + E_{en}. \quad (42.17)$$

The lowest value is thus equal to $(E_g + E_{h1} + E_{e1})$, which shows that the optical band gap is shifted by the sum of the electron and hole confinement energies. Once the photon energy exceeds the threshold set by (42.17), a continuous band of absorption occurs with the absorption coefficient independent of energy due to the constant 2-D density of states of the quantum well. The difference between the absorption of an ideal quantum well with infinite barriers and the equivalent bulk semiconductor is illustrated in Fig. 42.5b. In the quantum well we find a series of steps with constant absorption coefficients, whereas in the bulk the absorption varies as

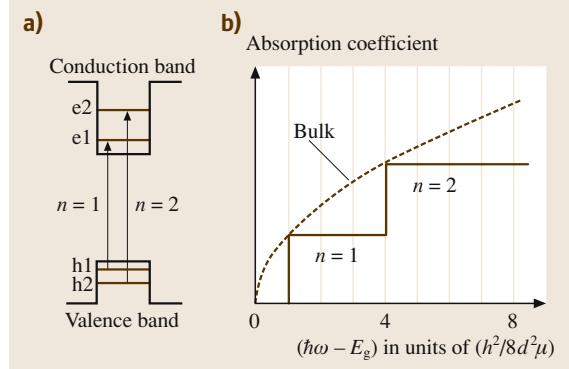

Fig. 42.5a,b Interband optical transitions between confined states in a quantum well. **(a)** Schematic diagram showing the $\Delta n = 0$ transitions between the $n = 1$ and $n = 2$ sub-bands. **(b)** Absorption spectrum for an infinite quantum well of thickness d with a reduced electron-hole mass μ in the absence of excitonic effects. The absorption spectrum of the equivalent bulk semiconductor is shown by the dashed line for comparison

$(\hbar\omega - E_g)^{1/2}$ for $\hbar\omega > E_g$. Thus the transition from 3-D to 2-D alters the shape of the absorption curve, and also causes an effective shift in the band gap by $(E_{h1} + E_{e1})$.

Up to this point, we have neglected the Coulomb interaction between the electrons and holes which are involved in the transition. This attraction leads to the formation of bound electron-hole pairs called excitons. The exciton states of a quantum well can be modelled as 2-D hydrogen atoms in a material with relative dielectric constant ϵ_r . In this case, the binding energy E^X is given by [42.12]:

$$E^X(v) = \frac{\mu}{m_0} \frac{1}{\epsilon_r^2} \frac{1}{(v - 1/2)^2} R_H, \quad (42.18)$$

where v is an integer ≥ 1 , m_0 is the electron mass, μ is the reduced mass of the electron-hole pair, and R_H is the Rydberg constant for hydrogen (13.6 eV). This contrasts with the standard formula for 3-D semiconductors in which E^X varies as $1/v^2$ rather than $1/(v - 1/2)^2$, and implies that the binding energy of the ground-state exciton is four times larger in 2-D than 3-D. This allows excitonic effects to be observed at room temperature in quantum wells, whereas they are only usually observed at low temperatures in bulk semiconductors.

Figure 42.6 compares the band-edge absorption of a GaAs MQW sample with that of bulk GaAs at room temperature [42.13]. The MQW sample contained 77 GaAs quantum wells of thickness 10 nm with thick $\text{Al}_{0.28}\text{Ga}_{0.72}\text{As}$ barriers separating them. The shift of

Fig. 42.6 Absorption spectrum of a 77-period GaAs/Al_{0.28}Ga_{0.72}As MQW structure with 10-nm quantum wells at room temperature. The absorption spectrum of bulk GaAs is included for comparison. (After [42.13], © 1982 AIP)

the band edge of the MQW to higher energy is clearly observed, together with the series of steps due to each $\Delta n = 0$ transition. The sharp lines are due to excitons, which occur at energies given by

$$\hbar\omega = E_g + E_{hh1} + E_{el} - E^X. \quad (42.19)$$

Equation (42.18) predicts that E^X should be around 17 meV for the ground-state exciton of an ideal GaAs quantum well, compared to 4.2 meV for the bulk. The actual QW exciton binding energies are somewhat smaller due to the tunnelling of the electrons and holes into the barriers, with typical values of around 10 meV. However, this is still substantially larger than the bulk value and explains why the exciton lines are so much better resolved for the QW than the bulk. The absorption spectrum of the QW above the exciton lines is approximately flat due to the constant density of states in 2-D, which contrasts with the rising absorption of the bulk due to the parabolic 3-D density of states. Separate transitions are observed for the heavy and light holes. This follows from their different effective masses, and can also be viewed as a consequence of the lower symmetry of the QW compared to the bulk.

Emission

Emissive transitions occur when electrons excited in the conduction band drop down to the valence band and recombine with holes. The optical intensity $I(\hbar\omega)$ is proportional to the transition rate given by (42.14) multiplied by the probability that the initial state is occupied

Fig. 42.7 Schematic band diagram and wave functions for a quantum well in a DC electric field F

and the final state is empty:

$$I(\hbar\omega) \propto W(c \rightarrow v) f_c (1 - f_v), \quad (42.20)$$

where f_c and f_v are the Fermi–Dirac distribution functions in the conduction and valence bands, respectively. In thermal equilibrium, the occupancy of the states is largest at the bottom of the bands and decays exponentially at higher energies. Hence the luminescence spectrum of a typical GaAs QW at room temperature usually consists of a peak of width $\sim k_B T$ at the effective band gap of $(E_g + E_{hh1} + E_{el})$. At lower temperatures the spectral width is affected by inhomogeneous broadening due to unavoidable fluctuations in the well thickness. Furthermore, in quantum wells employing alloy semiconductors, the microscopic fluctuations in the composition can lead to additional inhomogeneous broadening. This is particularly true of InGa_N/Ga_N quantum wells, where indium compositional fluctuations produce substantial inhomogeneous broadening even at room temperature.

The intensity of the luminescence peak in quantum wells is usually much larger than that of bulk materials because the electron–hole overlap is increased by the confinement. This leads to faster radiative recombination, which then wins out over competing nonradiative decay mechanisms and leads to stronger emission. This enhanced emission intensity is one of the main reasons why quantum wells are now so widely used in diode lasers and light-emitting diodes.

42.2.3 The Quantum-Confined Stark Effect

The *quantum-confined Stark effect* (QCSE) describes the response of the confined electron and hole states in quantum wells to a strong direct-current (DC) electric field applied in the growth (z) direction. The field is

usually applied by growing the quantum wells inside a p–n junction, and then applying reverse bias to the diode. The magnitude of the electric field F is given by:

$$F = \frac{V^{\text{built-in}} - V^{\text{bias}}}{L_i}, \quad (42.21)$$

where $V^{\text{built-in}}$ is the built-in voltage of the diode, V^{bias} is the bias voltage, and L_i is the total thickness of the intrinsic region. $V^{\text{built-in}}$ is approximately equal to the band-gap voltage of the doped regions (≈ 1.5 V for a GaAs diode).

Figure 42.7 gives a schematic band diagram of a quantum well with a strong DC electric field applied. The field tilts the potential and distorts the wave functions as the electrons tend to move towards the anode and the holes towards the cathode. This has two important consequences for the optical properties. Firstly, the lowest transition shifts to lower energies due to the electrostatic interaction between the electric dipole induced by the field and the field itself. At low fields the dipole is proportional to F , and the red shift is thus proportional to F^2 (the quadratic Stark effect). At higher fields, the dipole saturates at a value limited by ed , where e is the electron charge and d the well width, and the Stark shift is linear in F . Secondly, the parity selection rule no longer applies due to the breaking of the inversion symmetry about the centre of the well. This means that *forbidden* transitions with Δn equal to an odd number become allowed. At the same time, the $\Delta n = 0$ transitions grad-

ually weaken with increasing field as the distortion to the wave functions reduces the electron–hole overlap.

Figure 42.8 shows the normalised room-temperature photocurrent spectra of a GaAs/Al_{0.3}Ga_{0.7}As MQW p–i–n diode containing 9.0-nm quantum wells at 0 V and –10 V applied bias. These two bias values correspond to field strengths of around 15 kV/cm and 115 kV/cm respectively. The photocurrent spectrum closely resembles the absorption spectrum, due to the field-induced escape of the photoexcited carriers in the QWs into the external circuit (Sect. 42.2.5). The figure clearly shows the Stark shift of the absorption edge at the higher field strength, with a red shift of around 20 meV (≈ 12 nm) at –10 V bias for the hh1 \rightarrow e1 transition. The intensity of the line weakens somewhat due to the reduction in the electron–hole overlap, and there is lifetime broadening caused by the field-assisted tunnelling. Several parity-forbidden transitions are clearly observed. The two most obvious ones are identified with arrows, and correspond to the hh2 \rightarrow e1 and hh1 \rightarrow e2 transitions, respectively.

A striking feature in Fig. 42.8 is that the exciton lines are still resolved even at very high field strengths. In bulk GaAs the excitons ionise at around 5 kV/cm [42.11], but in QWs the barriers inhibit the field ionisation, and excitonic features can be preserved even up to ≈ 300 kV/cm [42.14]. The ability to control the absorption spectrum by the QCSE is the principle behind a number of important modulator devices, which will be discussed in Sect. 42.5.

In the case of a superlattice, such as that illustrated in Fig. 42.3, a strong perpendicular electric field can break the minibands into discrete energy levels local to each QW, due to the band-gap tilting effect represented in Fig. 42.7. The possibility of using an electric field to modify the minibands of a superlattice is yet another remarkable ability of band-gap engineering to achieve control over the electronic properties by directly using fundamental principles of quantum mechanics.

42.2.4 Inter-Sub-Band Transitions

The engineered band structure of quantum wells leads to the possibility of *inter-sub-band (ISB) transitions*, which take place between confined states within the conduction or valence bands, as illustrated schematically in Fig. 42.9. The transitions typically occur in the infrared spectral region. For example, the e1 \leftrightarrow e2 ISB transition in a 10-nm GaAs/AlGaAs quantum well occurs at around 15 μm . For ISB absorption transitions we must first dope the conduction band so that there is a large population of electrons in the e1 level, as shown

Fig. 42.8 Room-temperature photocurrent spectra for a GaAs/Al_{0.3}Ga_{0.7}As MQW p–i–n diode with a 1- μm -thick i-region at zero bias and –10 V. The quantum well thickness was 9.0 nm. The arrows identify transitions that are forbidden at zero field. (After [42.14], © 1991 IEEE)

Fig. 42.9 (a) Inter-sub-band absorption in an n-type quantum well. (b) Inter-sub-band emission following electron injection to a confined upper level in the conduction band

in Fig. 42.9a. This is typically achieved by n-type doping of the barriers, which produces a large electron density as the extrinsic electrons drop from the barriers to the confined states in the QW. Undoped wells are used for ISB emission transitions, and electrons must first be injected into excited QW states, as shown in Fig. 42.9b.

The basic properties of ISB transitions can be understood by extension of the principles outlined in Sect. 42.2.2. The main difference is that the envelope functions for the initial and final states are the same, since both states lie in the same band. The transition rate for a conduction-band ISB transition then turns out to be given by:

$$W^{\text{ISB}} \propto |\langle \psi_{en'}(z) | z | \psi_{en}(z) \rangle|^2 g(\hbar\omega), \quad (42.22)$$

where n and n' are the quantum numbers for the initial and final confined levels. The z operator within the Dirac bracket arises from the electric-dipole interaction and indicates that the electric field of the light wave must be parallel to the growth direction. Furthermore, the odd parity of the z operator implies that the wave functions must have different parities, and hence that Δn must be an odd number. The use of ISB transitions in infrared emitters and detectors will be discussed in Sects. 42.3.2, 42.4.3 and 42.4.4.

42.2.5 Vertical Transport

Quantum Wells

Vertical transport refers to the processes by which electrons and holes move in the growth direction. Issues relating to vertical transport are important for the efficiency and frequency response of most QW optoelectronic devices. The transport is generally classified as either *bipolar*, when both electrons and holes are involved, or *unipolar*, when only one type of carrier (usually electrons) is involved. In this section we will concentrate primarily on bipolar transport in QW detectors and QCSE modulators. Bipolar transport in light-emitting devices is discussed in Sects. 42.2.6

and 42.3.1, while unipolar transport in quantum cascade lasers is discussed in Sect. 42.3.2.

In QW detectors and QCSE modulators the diodes are operated in reverse bias. This produces a strong DC electric field and tilts the bands as shown in Fig. 42.7. Electrons and holes generated in the quantum wells by absorption of photons can escape into the external circuit by tunnelling and/or thermal emission, as illustrated schematically in Fig. 42.7.

The physics of tunnelling in quantum wells is essentially the same as that of α -decay in nuclear physics. The confined particle oscillates within the well and attempts to escape every time it hits the barrier. The escape rate is proportional to the attempt frequency ν_0 and the transmission probability of the barrier. For the simplest case of a rectangular barrier of thickness b , the escape time τ_T is given by:

$$\frac{1}{\tau_T} = \nu_0 \exp(-2\kappa b), \quad (42.23)$$

where κ is the tunnelling decay constant given by (42.10). The factor of 2 in the exponential arises due to the dependence of the transmission probability on $|\psi(z)|^2$. The situation in a biased quantum well is more complicated due to the non-rectangular shape of the barriers. However, (42.23) allows the basic trends to be understood. To obtain fast tunnelling we need thin barriers and small κ . The second requirement is achieved by keeping m_b^* as small as possible and by working with a small confining potential V_0 . The tunnelling rate increases with increasing field, because the average barrier height decreases.

The thermal emission of electrons over a confining potential is an old problem which was originally applied to the heated cathodes in vacuum tubes. It has been shown that the thermal current fits well to the classical Richardson formula:

$$J_E \propto T^{1/2} \exp\left(-\frac{e\Phi}{k_B T}\right), \quad (42.24)$$

with the work function Φ replaced by $[V(F) - E_n]$, $V(F)$ being the height of the barrier that must be overcome at the field strength F [42.15]. The emission rate is dominated by the Boltzmann factor, which represents the probability that the carriers have enough thermal kinetic energy to escape over the top of the barrier. At low fields $V(F) \approx (V_0 - E_n)$, but as the field increases, $V(F)$ decreases as the barriers tilt over. Hence the emission rate (like the tunnelling rate) increases with increasing field. The only material-dependent parameter that enters the Boltzmann factor is the barrier height. Since this is insensitive both to the effective masses and to the barrier

Fig. 42.10 Schematic representation of the drift of injected carriers and their subsequent capture by quantum wells. Light emission occurs when electrons and holes are captured in the same quantum well and then recombine with each other

thickness, the thermal emission rate can dominate over the tunnelling rate in some conditions, especially at room temperature in samples with thick barriers. For example, the fastest escape mechanism in GaAs/Al_{0.3}Ga_{0.7}As QWs at room temperature can be the thermal emission of holes, which have a much smaller barrier to overcome than the electrons [42.16].

Superlattices

The artificial periodicity of superlattice structures gives rise to additional vertical transport effects related to the phenomenon of Bloch oscillations. It is well known that an electron in a periodic structure is expected to oscillate when a DC electric field is applied. This effect has never been observed in natural crystals because the oscillation period – equal to h/eFa , where a is the unit cell size – is much longer than the scattering times of the electrons. In a superlattice, by contrast, the unit cell size is equal to $(d+b)$ (See Fig. 42.3) and the oscillation period can be made much shorter. This allows the electron to perform several oscillations before being scattered. The oscillatory motion of the electrons in a superlattice was first observed by two groups in 1992 [42.17, 18]. The following year, another group directly detected the radiation emitted by the oscillating electron wave packet [42.19]. The subject has since developed greatly, and THz-frequency emission has now been achieved from GaAs/AlGaAs superlattices even at room temperature [42.20].

42.2.6 Carrier Capture and Relaxation

In a QW light-emitting device, the emission occurs after carriers injected from the contacts are transported to the active region and then captured by the QWs. The

capture and subsequent relaxation of the carriers is thus of crucial importance. Let us consider the band-edge profile of a typical QW diode-laser active region, as illustrated in Fig. 42.10. The active region is embedded between larger band-gap cladding layers designed to prevent thermally assisted carrier leakage outside the active region. Electrons and holes are injected from the n- and p-doped cladding layers under forward bias and light emission follows after four distinct processes have taken place: (1) relaxation of carriers from the cladding layers to the confinement barriers (CB); (2) carrier transport across the CB layers, by diffusion and drift; (3) carrier capture into the quantum wells; and (4) carrier relaxation to the fundamental confined levels.

The carrier relaxation to the CB layers occurs mainly by longitudinal optical (LO) phonon emission. The CB layer transport is governed by a classical electron fluid model. The holes are heavier and less mobile than the electrons, and hence the ambipolar transport is dominated by the holes. Carrier nonuniformities, such as carrier pile up at the p-side CB region due to the lower mobility of the holes, are taken into account in the design of the barrier layers. The carrier capture in the QWs is governed by the phonon-scattering-limited carrier mean free path. It is observed experimentally that the capture time oscillates with the QW width. Detailed modelling reveals that this is related to a resonance between the LO phonon energy and the energy difference between the barrier states and the confined states within the well [42.21]. As another design guideline, the QW widths must be larger or at least equal to the phonon-scattering-limited carrier mean free path at the operating temperature in order to speed up the carrier capture. Finally, the relaxation of carriers to the lowest sub-band occurs on a sub-picosecond time scale if the inter-sub-band energy separation is larger than the LO phonon energy. Carrier-carrier scattering can also contribute to an ultrafast thermalisation of carriers, on a femtosecond time scale at the high carrier densities present inside laser diodes. Many of these processes have been studied in detail by ultrafast laser spectroscopy [42.22].

Carrier capture and escape are complementary vertical transport mechanisms in MQW structures. In the design of vertical transport-based MQW devices, one process must often be sped up at the expense of making the other as slow as possible. For example, in order to enhance the performance of QW laser diodes, the carrier confinement capability of the MQW active region must be optimised in terms of minimising the ratio between the carrier capture and escape times [42.23].

42.3 Emitters

42.3.1 Interband Light-Emitting Diodes and Lasers

Quantum wells have found widespread use in light-emitting diode (LED) and laser diode applications for a number of years now. As discussed in Sects. 42.1.2 and 42.2.2, there are three main reasons for this. Firstly, the ability to control the quantum-confinement energy provides an extra degree of freedom to engineer the emission wavelength. Secondly, the change of the density of states and the enhancement of the electron-hole overlap leads to superior performance. Finally, the ability to grow strained layers of high optical quality greatly increases the variety of material combinations that can be employed, thus providing much greater flexibility in the design of the active regions.

Much of the early work concentrated on lattice-matched combinations such as GaAs/AlGaAs on GaAs substrates. GaAs/AlGaAs QW lasers operating around 800 nm has now become industry-standard for applications in laser printers and compact discs. Furthermore, the development of high-power arrays has opened up new applications for pumping solid-state lasers such as Nd : YAG. Other types of lattice-matched combinations can be used to shift the wavelength into the visible spectral region and also further into the infrared. QWs based on the quaternary alloy $(\text{Al}_y\text{Ga}_{1-y})_x\text{In}_{1-x}\text{P}$, are used for red-emitting laser pointers [42.24], while $\text{Ga}_{0.47}\text{In}_{0.53}\text{As}$ QWs and its variants incorporating Al are used for the important telecommunication wavelengths of 1300 nm and 1550 nm.

The development of strained-layer QW lasers has greatly expanded the range of material combinations that are available. The initial work tended to focus on $\text{In}_x\text{Ga}_{1-x}\text{As}/\text{GaAs}$ QWs grown on GaAs substrates. The incorporation of indium into the quantum well shifts the band edge to lower energy, thereby giving emission in the wavelength range 900–1100 nm. An important technological driving force has been the need for powerful sources at 980 nm to pump erbium-doped fibre amplifiers [42.25]. Furthermore, as mentioned in Sect. 42.2.1, the strain alters the band structure and this can have other beneficial effects on the device performance. For example, the compressive strain in the $\text{In}_x\text{Ga}_{1-x}\text{As}/\text{GaAs}$ QW system has been exploited in greatly reducing the threshold current density. This property is related to the reduced effective mass of the holes and hence the reduced density of states. An extensive account of the effects of strain on semiconductor

layers and the performance of diode lasers is given in [42.26].

At the other end of the spectral range, a spectacular development has been the $\text{In}_x\text{Ga}_{1-x}\text{N}/\text{GaN}$ QWs grown on sapphire substrates. These highly strained QWs are now routinely used in ultrabright blue and green LEDs, and there is a growing interest in developing high-power LED sources for applications in solid-state lighting [42.27]. Commercial laser diodes operating around 400 nm have been available for several years [42.8], and high-power lasers suited to applications in large-capacity optical disk video recording systems have been reported [42.28]. Lasers operating out to 460 nm have been demonstrated [42.29], and also high-efficiency ultraviolet light-emitting diodes [42.30]. At the same time, much progress has been made in the application of AlGaIn/GaN quantum-well materials in high-power microwave devices [42.31, 32].

A major application of quantum wells is in *vertical-cavity surface-emitting lasers (VCSELs)*. These lasers emit from the top of the semiconductor surface, and have several advantages over the more-conventional edge-emitters: arrays are readily fabricated, which facilitates their manufacture; no facets are required, which avoids complicated processing procedures; the beam is circular, which enhances the coupling efficiency into

Fig. 42.11 Schematic diagram of a vertical-cavity surface-emitting laser (VCSEL). The quantum wells (QWs) that comprise the gain medium are placed at the centre of the cavity formed between two distributed Bragg reflector (DBR) mirrors. Oxidised or proton-implanted regions provide the lateral confinement for both the current and the optical mode

optical fibres; and their small size leads to very low threshold currents. For these reasons the development of VCSELs has been very rapid, and many local-area fibre networks operating around 850 nm currently employ VCSEL devices. This would not have been possible without the high gain coefficients that are inherent to the QW structures.

Figure 42.11 gives a schematic diagram of a typical GaAs-based VCSEL. The device contains an active QW region inserted between two distributed Bragg reflector (DBR) mirrors consisting of AlGaAs quarter-wave stacks made of alternating high- and low-refractive-index layers. The structure is grown on an n-type GaAs substrate, and the mirrors are appropriately doped n- or p-type to form a p-n junction. Electrons and holes are injected into the active region under forward bias, where they are captured by the QWs and produce gain at the lasing wavelength λ . The quantum wells are contained within a transparent layer of thickness $\lambda/2n_0$, where n_0 is the average refractive index of the active region. The light at the design wavelength is reflected back and forth through the gain medium and adds up constructively, forming a laser resonator. Oxidised or proton-implanted regions provide lateral confinement of both the current and the optical mode. Reviews of the design and properties of VCSELs may be found in [42.34] and [42.35].

The conventional VCSEL structures grown on GaAs substrates operate in the wavelength range 700–1100 nm [42.36]. Some of these structures are lattice-matched, but others – notably the longer-wavelength devices which incorporate strained InGaAs quantum wells – are not. Much work is currently focussed on extending the range of operation to the telecommunication wavelengths of 1300 nm and 1550 nm. Unfortunately, it is hard to grow DBR mirrors with sufficient reflectivity on InP substrates due to the low refractive-index contrast of the materials, and thus progress has been slow. Recent alternative approaches based on GaAs substrates will be mentioned in Sect. 42.6.

Resonator structures such as the VCSEL shown in Fig. 42.11 can be operated below threshold as resonant-cavity LEDs (RCLEDs). The presence of the cavity reduces the emission line width and hence increases the intensity at the peak wavelength [42.37]. Furthermore, the narrower line width leads to an increase in the bandwidth of the fibre communication system due to the reduced chromatic dispersion [42.38]. A review of the progress in RCLEDs is given in [42.39].

42.3.2 Quantum Cascade Lasers

The principles of infrared emission by ISB transitions were described in Sect. 42.2.4. Electrons must first be injected into an upper confined electron level as shown in Fig. 42.9b. Radiative transitions to lower confined states with different parities can then occur. ISB emission is usually very weak, as the radiative transitions have to compete with very rapid nonradiative decay by phonon emission, (Sect. 42.2.6). However, when the electron density in the upper level is large enough, population inversion can occur, giving rapid stimulated emission and subsequent laser operation. This is the operating concept of the *quantum cascade (QC) laser* first demonstrated in 1994 [42.40]. The laser operated at 4.2 μm at temperatures up to 90 K. Although the threshold current for the original device was high, progress in the field had been very rapid. A comprehensive review of the present state of the art is given in [42.33], while a more introductory overview may be found in [42.41].

Fig. 42.12 Conduction band diagram for two active regions of an InGaAs/AlInAs quantum cascade laser, together with the intermediate miniband injector region. The levels in each active region are labelled according to their quantum number n , and the corresponding wave function probability densities are indicated. Laser transitions are indicated by the wavy arrows, while electron tunnelling processes are indicated by the straight arrows. (After [42.33], © 2001 IOP)

The quantum-well structures used in QC lasers are very complicated, and often contain hundreds of different layers. Figure 42.12 illustrates a relatively simple design based on lattice-matched $\text{In}_{0.47}\text{Ga}_{0.53}\text{As}/\text{Al}_{0.48}\text{In}_{0.52}\text{As}$ quantum wells grown on an InP substrate. The diagram shows two active regions and the miniband injector region that separates them. A typical operational laser might contain 20–30 such repeat units. The population inversion is achieved by resonant tunnelling between the $n = 1$ ground state of one active region and the $n = 3$ upper laser level of the next one. The basic principles of this process were enunciated as early as 1971 [42.42], but it took more than 20 years to demonstrate the ideas in the laboratory. The active regions contain asymmetric coupled quantum wells, and the laser transition takes place between the $n = 3$ and $n = 2$ states of the coupled system. The separation of the $n = 2$ and $n = 1$ levels is carefully designed to coincide with the LO-phonon energy, so that very rapid relaxation to the ground state oc-

curs and the system behaves as a four-level laser. This latter point is crucial, since the lifetime of the upper laser level is very short (typically ≈ 1 ps), and population inversion is only possible when the lifetime of the lower laser level is shorter than that of the upper one. The lasing wavelength can be varied by detailed design of the coupled QW active region. The transition energy for the design shown in Fig. 42.12 is 0.207 eV, giving emission at $6.0\text{ }\mu\text{m}$. Further details may be found in [42.33].

A very interesting recent development has been the demonstration of a QC laser operating in the far-infrared spectral region at $67\text{ }\mu\text{m}$ [42.43]. Previous work in this spectral region had been hampered by high losses due to free-carrier absorption and the difficulties involved in designing the optical waveguides. The device operated up to 50 K and delivered 2 mW. These long-wavelength devices are required for applications in the THz frequency range that bridges between long-wavelength optics and high-frequency electronics.

42.4 Detectors

Photodetectors for the visible and near-infrared spectral regions are generally made from bulk silicon or III–V alloys such as GaInAs. Since these devices work very well, the main application for QW photodetectors is in the infrared spectral region and for especially demanding applications such as avalanche photodiodes and solar cells. These three applications are discussed separately below, starting with solar cells.

42.4.1 Solar Cells

The power generated by a solar cell is determined by the product of the photocurrent and the voltage across the diode. In conventional solar cells, both of these parameters are determined by the band gap of the semiconductor used. Large photocurrents are favoured by narrow-gap materials, because semiconductors only absorb photons with energies greater than the band gap, and narrow-gap materials therefore absorb a larger fraction of the solar spectrum. However, the largest open-circuit voltage that can be generated in a p–n device is the built-in voltage which increases with the band gap of the semiconductor. Quantum-well devices can give better performance than their bulk counterparts because they permit separate optimisation of the current- and voltage-generating factors [42.44]. This is because the built-in voltage is

primarily determined by the band gap of the barrier regions, whereas the absorption edge is determined by the band gap of the quantum wells. The drawback in using quantum wells is that it is difficult to maintain high photocurrent quantum efficiency in the low-field forward-bias operating conditions in solar cells.

Recent work in this field has explored the added benefits of the versatility of the design of the QW active region [42.45] and also the possibility of using strained QWs. In the latter case, a tradeoff arises between the increase in both the absorption and the number of interface dislocations (which act as carrier traps) with the number of QWs. A way round this compromise is to use strain balance. An example is the case of $\text{In}_x\text{Ga}_{1-x}\text{As}/\text{GaAs}_{0.94}\text{P}_{0.06}$ QW solar cells grown on GaAs substrates, in which the compressive strain of the InGaAs QWs is compensated with the tensile-strained $\text{GaAs}_{0.94}\text{P}_{0.06}$ barriers, such that the overall active region could be successfully lattice-matched to the substrate [42.46].

42.4.2 Avalanche Photodiodes

Avalanche photodiodes (APDs) are the detectors of choice for many applications in telecommunications and single-photon counting. The avalanche multiplica-

Fig. 42.13 Schematic representation of an InGaAs/InP/InGaAsP/InAlAs superlattice avalanche photodiode (SL-APD). Light is absorbed in the bulk InGaAs layer and the resulting photocurrent is multiplied by the avalanche process in the InGaAsP/InAlAs superlattice region. The spatial periodicity of the superlattice reduces the dark current

tion mechanism plays a critical role in determining the photodetection gain, the noise and the gain-bandwidth product. Commercially available III–V semiconductor APDs are typically engineered with different band-gap materials in the absorption and multiplication regions [42.47]. The absorption layer has a relatively narrow band gap (such as $\text{In}_{0.53}\text{Ga}_{0.47}\text{As}$) to allow for larger absorption, whereas the multiplication region has a wider band gap (such as InP or $\text{In}_{0.52}\text{Al}_{0.48}\text{As}$) to reduce the dark current at the high electric fields required. It has been demonstrated that the dark current can be further reduced by incorporating adequately designed superlattices into the multiplication layer to form a *superlattice avalanche photodiode* (SL-APD) as shown in Fig. 42.13 [42.48]. Essentially, the miniband formation (Fig. 42.3) in the SL corresponds to a larger effective band gap and thus reduces the probability of band-to-band tunnelling at the high electric fields required for carrier impact ionisation and subsequent carrier multiplication.

It has been proposed that the excess noise factor can be reduced further by designing multiplication layers with SL [42.49] or *staircase* [42.50] structures to enhance the ionisation rate of one carrier type relative to the other due to their different band-edge discontinuities [42.51]. However, this proposal is still under active theoretical and experimental scrutiny, because most of the electrons populate the higher energy satellite valleys (X and L) at the high electric fields required for avalanche gain [42.52]. Recent Monte Carlo

simulations [42.53], backed up by experimental evidence [42.54], have shown that the ratio of the electron and hole ionisation rates, commonly used as a figure of merit in bulk multiplication layers [42.55], is not critically affected by the band-gap discontinuities. In fact, these recent models emphasise that it is the spatial modulation of the impact ionisation probability, associated with the periodic band-gap discontinuity, which leads to a reduction in the multiplication noise.

42.4.3 Inter-Sub-Band Detectors

The principles of infrared absorption by ISB transitions were described in Sect. 42.2.4. Infrared detectors are required for applications in defence, night vision, astronomy, thermal mapping, gas-sensing, and pollution monitoring. *Quantum-well inter-sub-band photodetectors* (QWIPs) are designed so that the energy separation of the confined levels is matched to the chosen wavelength. A major advantage of QWIPs over the conventional approach employing narrow-gap semiconductors is the use of mature GaAs-based technologies. Furthermore, the detection efficiency should in principle be high due to the large oscillator strength that follows from the parallel curvature of the in-plane dispersions for states within the same bands [42.56]. However, technical challenges arise from the requirement that the electric field of the light must be polarised along the growth (z) direction. This means that QWIPs do not work at normal incidence, unless special steps are taken to introduce a component of the light field along the z -direction. Various approaches have been taken for optimum light coupling, such as using bevelled edges, gratings or random reflectors [42.57].

Despite their promising characteristics, QWIPs have yet to be commercialised. The main issue is the high dark current at higher operating temperatures. The dark current is governed by the thermionic emission of ground-state electrons directly out of the QW above 45 K [42.58]. Overcoming such technical difficulties has made possible the demonstration of long-wavelength large-format focal-plane array cameras based on ISB transitions [42.59].

42.4.4 Unipolar Avalanche Photodiodes

The combination of resonant inter-sub-band (ISB) photodetection (Sect. 42.4.3) and avalanche multiplication has been studied for exploiting the possibility of designing a unipolar avalanche photodiode (UAPD) [42.60]. UAPDs rely on impact ionisation involving only one

Fig. 42.14 Unipolar carrier multiplication in a multiple QW structure at field strength F : (1) is the primary electron resulting from photodetection, while (2) is the secondary electron resulting from the impact ionisation of the QW by the primary electron

type of carrier in order to achieve gain in photoconductive detectors for mid- and far-infrared light. The unipolar impact ionisation occurs when the kinetic energy of the primary carrier exceeds an activation energy E_a defined as the transition energy between the QW ground state and the QW top state (Fig. 42.14). A single QW then releases an extra electron each time it is subject to an impact with an incoming electron.

The impact ionisation probability for this process is given by the product between the carrier capture probability and the carrier escape probability under

a mechanism of carrier–carrier scattering in the QW. The subsequent electron transport towards further multiplication events occurs through a sequence of escape, drift and kinetic energy gain under the applied electric field, relaxation, capture and QW ionisation. Ultimately, the multiplication gain in an UAPD is governed by the QW capture probability, the number of QWs and the field uniformity over the QW sequence. The unipolar nature of the multiplication process must be preserved in order to avoid field nonuniformities stemming from spatial-charge variation caused by bipolar carrier transport across the multiplication region.

Interest in a purely unipolar multiplication mechanism was originally motivated by the possibility of reduced noise in comparison to bipolar APDs (Sect. 42.4.2), where band-to-band transitions lead to gain fluctuations manifested as excess noise [42.55]. For this purpose, the QWs in an UAPD structure are typically tailored such that the inter-sub-band activation energy E_a is smaller than the inter-band impact ionisation activation energy that would be responsible for bipolar avalanche multiplication. However, recent studies have shown that unipolar avalanche multiplication is also accompanied by an excess noise factor, such that the noise gain exceeds the photoconductive gain [42.61], thus limiting the practical applications of UAPDs.

42.5 Modulators

In Sect. 42.2.3 we noted that the optical properties of quantum-well diodes are strongly modified by the application of voltages through the quantum-confined Stark effect (QCSE). Referring to Fig. 42.8, we see that at wavelengths below the heavy-hole exciton at 0 V, the absorption increases as the voltage is applied, which provides a mechanism for the modulation of light. For example, the amount of light transmitted at wavelengths close to the band edge would change with the voltage applied. Moreover, since changes of absorption are accompanied by changes of the refractive index through the Kramers–Kronig relationship, it is possible to make QCSE phase modulators as well [42.62]. In addition to the standard GaAs/AlGaAs devices operating around 800 nm, QCSE modulators have been demonstrated in several other material systems, such as GaInAs-based structures for the important telecommunications wavelength at 1.5 μm [42.63].

The operation of GaAs-based QCSE transmission modulators at normal incidence is hampered

by the fact that the substrates are opaque at their operating wavelength. One way round this problem

Fig. 42.15 Schematic diagram of an integrated quantum-well waveguide electroabsorption modulator (EAM) and distributed feedback (DFB) laser. The laser is forward-biased while the EAM is reverse-biased. The p-contacts of the two electrically independent devices are separated by proton implantation. The light emitted by the laser is guided through the EAM region, resulting in a modulated output beam when data pulses are applied to the EAM

is to etch the substrate away, but this is a difficult process, and a much better solution is to include a mirror underneath the quantum wells so that the modulated light does not have to pass through the substrate [42.64]. In many practical applications, however, mostly involving the integration of **QCSE** modulators with **MQW** light emitters on a common substrate, the waveguide geometry is the configuration of choice [42.65]. In this architecture, the light beam propagates along the waveguide from the emitter to the *electroabsorption modulator* (EAM) region, as shown in Fig. 42.15. The **QCSE** modulator transmits the incoming laser light when no voltage is applied and absorbs the beam when the **MQW** stack is suitably biased.

The most successful commercial impact of **QCSE** modulators has been in the integration of EAMs with distributed feedback (**DFB**) or distributed Bragg reflector (**DBR**) **MQW** diode lasers in waveguide configurations, as shown in Fig. 42.15. These devices have been used for optical coding in the C-band (1525–1565 nm), at 10 Gb/s or higher data transmission speeds [42.66]. The

combination of a continuous laser and a high-speed modulator offers better control of the phase chirp of the pulses than direct modulation of the laser output itself [42.67]. In particular, the chirp factor is expected to become negative if the photogenerated carriers can be swept out fast enough in the EAM, which is desirable for long-distance data transmission through optical fibers [42.68].

A promising step toward the merger between band-gap-engineered semiconductors and mature very-large-scale integration (VLSI) silicon architectures has been achieved when III–V semiconductor **QCSE** modulator structures have been integrated with state-of-the-art silicon complementary metal–oxide–semiconductor (**CMOS**) circuitry [42.69]. Through this hybrid technology, thousands of optical inputs and outputs could be provided to circuitry capable of very complex information processing. The idea of using light beams to replace wires in telecommunications and digital computer systems has thus become an attractive technological avenue in spite of various challenges implied [42.70].

42.6 Future Directions

The subject of quantum-confined semiconductor structures moves very rapidly and it is difficult to see far into the future. Some ideas have moved very quickly from the research labs into the commercial sector (e.g. **VCSELs**), while others (e.g. quantum cascade lasers) have taken many years to come to fruition. We thus restrict ourselves here to a few comments based on active research fields at the time of writing.

One idea that is being explored in detail is the effects of lower dimensionality in quantum-wire and quantum-dot structures (Table 42.1). Laser operation from one-dimensional (1-D) GaAs quantum wires was first demonstrated in 1989 [42.72], but subsequent progress has been relatively slow due to the difficulty in making the structures. By contrast, there has been an explosion of interest in zero-dimensional (0-D) structures following the discovery that quantum dots can form spontaneously during **MBE** growth in the Stranski–Krastanow regime. A comprehensive review of this subject is given in [42.73].

Figure 42.16 shows an electron microscope image of an InAs quantum dot grown on a GaAs crystal by the Stranski–Krastanow technique. The dots are formed because of the very large mismatch between the lattice constants of the InAs and the underlying GaAs.

The strain that would be produced in a uniform layer is so large that it is energetically favourable to form small clusters. This then leads to the formation of islands of InAs with nanoscale dimensions, which can then be encapsulated within an optoelectronic structure by overgrowth of further GaAs layers.

The ability to grow quantum-dot structures directly by **MBE** has led to very rapid progress in the deployment of quantum dots in a variety of applications. It remains unclear at present whether quantum dots really lead to superior laser performance [42.74]. The intrinsic

Fig. 42.16 Transmission electron microscope image of an uncapped InAs quantum dot grown on GaAs by the Stranski–Krastanow technique. (After [42.71], © 2000 APS)

sic gain of the dots is higher than that of a quantum well [42.75], and the threshold current is less sensitive to temperature [42.76]. However, the volume of the gain medium is necessarily rather small, and the benefits of the lower dimensionality cannot be exploited to the full. At present, one of the most promising applications for quantum dots is in long-wavelength lasers [42.77]. As mentioned in Sect. 42.3.1, the production of VCSELs at 1300 nm and 1550 nm has proven to be difficult using conventional InP-based QW structures due to the low refractive-index contrast of the materials that form the DBR mirrors. The use of InAs/GaAs quantum dots as the active region circumvents this problem and allows the benefits of mature GaAs-based VCSEL technology.

Another very exciting potential application for quantum dots is in quantum information processing. High-efficiency single-photon sources are required for quantum cryptography and also quantum computation using linear optics. Several groups have demonstrated

single photon emission after excitation of individual InAs quantum dots (see e.g. [42.78, 79]), and one group has demonstrated an electrically driven single-photon LED [42.80]. After these proofs of principle, the challenge now lies ahead to establish the quantum-dot sources in working quantum information-processing systems.

At the same time as exploring the effects of lower dimensionality, many other groups are working on new QW materials. One of the most promising recent developments is the dilute nitride system for applications in long-wavelength VCSELs and solar cells [42.81]. It has been found that the inclusion of a small fraction of nitrogen into GaAs leads to a sharp decrease in the band gap due to very strong band-bowing effects. This then allows the growth of InGaAsN structures that emit at 1300 nm on GaAs substrates [42.77, 82]. The field is developing very rapidly, with 1300-nm VCSELs and 1500-nm edge emitters already demonstrated [42.83, 84].

42.7 Conclusions

Semiconductor quantum wells are excellent examples of quantum mechanics in action. The reduced dimensionality has led to major advances in both the understanding of 2-D physics and the applied science of optoelectronics. In some cases, QWs have enhanced the performance of conventional devices (e.g. LEDs and edge-emitting lasers), and in others, they have led to radically new devices (e.g. VCSELs, quantum cascade lasers, QCSE

modulators). At present, the main commercial use for QW optoelectronic devices is in LEDs, laser diodes and QCSE modulators. It remains to be seen whether some of the other devices described here (QW solar cells, SL-APDs, QWIPs) will come to commercial fruition, and whether systems of lower dimensionality will eventually replace QWs in the same way that QWs have replaced bulk devices.

Glasses for Photonic Integration

Inorganic glasses are the workhorse materials of optics and photonics. In addition to offering a range of transparency windows, glasses provide flexibility of processing for the realization of fibers, films, and shaped optical elements. Traditionally, the main role of glass has been as a passive material. However, a significant attribute of glasses is their ability to incorporate dopants such as nanoparticles or active ions. Hence, glasses promise to play an increasingly important role in active photonics, as laser, amplification, switching, and nonlinear media.

For photonic integration, many of the attributes of glasses are particularly compelling. Glasses allow numerous options for thin film deposition and integration on arbitrary platforms. The possibility of controlling the viscosity of a glass during processing can be exploited in the realization of extremely low loss microphotonic waveguides, photonic crystals, and microcavities. The metastable nature of glass can enable the direct patterning of photonic elements by energetic beams.

This chapter provides an overview of these unique properties of glasses, from the perspectives of the technology options they afford and the

practical limitations they present. Further, an overview is provided of the main families of glassy inorganic films studied for integrated optics. Finally, the main features of rare earth doped glasses are reviewed, with an emphasis on their potential for implementation of compact integrated light sources and amplifiers.

Inorganic glasses have played a central role in optical science and technology, and more generally within the electrical and electronic engineering disciplines [43.1]. Amongst optical materials, the unique advantages of glasses are well known [43.2, 3]. Glasses can be worked relatively easily into various forms, such as bulk lenses, fibers, and thin films. This is dramatically illustrated by the modern technology for the manufacture of low-loss silica fibers, in which a hair-thin glass fiber (with tightly controlled geometrical and material properties) is drawn from a heated glass preform at rates as high as 20 m/s or greater [43.4]. Glass can be manufactured with excellent homogeneity and without grain boundaries, so that scattering of light is acceptably low. While perfect crystals typically exhibit even lower lev-

els of scattering, they are difficult to realize in large sizes and with arbitrary shapes. Optical losses in polycrystalline materials, on the other hand, are generally excessive due to scattering from grain boundaries. Finally, the standard glass compositions (oxide, halide, and chalcogenide glasses and hybrids of those) provide transparency windows from the UV to the mid-infrared (see Fig. 43.1). It has been estimated [43.2] that more than 90% of optical components are based on glasses. Given the massive worldwide installation of telecommunications fibers since the 1980s [43.5], and depending on the definition assigned to the term 'component', this statistic might actually be closer to 100%.

Befitting their central role in optical technology, there are numerous excellent reviews covering

the optical properties and photonic functionalities of glasses [43.3, 6]. Further, one of the distinguishing attributes of glasses is their flexibility of composition. Hundreds of commercial glasses are available, and many more have been studied in research laboratories and reported in the academic literature. Thus, it is not possible to capture the full range of glassy materials (even restricted to inorganic glasses) within a short review paper. The recent monograph by *Yamane and Asahara* [43.6] provides a comprehensive and highly recommended treatment of glass technology and its application to photonics. The present contribution has relatively modest aims:

1. With a focus specifically on *integrated* photonics, the main advantages of glasses are discussed and the most studied glass systems are reviewed in brief. Integrated photonics (integrated optics) refers to guided wave photonic devices fabricated on planar platforms. Glass substrates (with waveguides defined by ion diffusion) have played an important role in integrated optics, but the advantages of glasses (compared to crystalline materials such as III-V semiconductors or lithium niobate) are less compelling in that case. For this reason, emphasis is placed on glassy thin films that can enable photonic functionality on other substrates. In practice, substrates of interest might be printed circuit boards or semiconductor wafers.
2. For the most part, the discussion is restricted to inorganic glasses. Some reference is made to organic glasses, since their properties and advantages parallel those of inorganic glasses in many respects, and because certain practical aspects of organic glasses have received greater attention in the literature. Good reviews covering polymer materials for integrated photonics are available [43.8].
3. To date, the most important inorganic glass system for integrated photonics is the silica on silicon planar lightwave circuit (PLC) platform. Several recent papers [43.9, 10] provide an overview of that technology, so only brief mention is made here. Rather, the goal is to provide some insight on advantages that

Fig. 43.1 Transmission plots are shown for SiO_2 glass and some representative fluoride and chalcogenide glasses. ZBLAN and BIG are heavy-metal fluoride glasses, 2SG is a selenide glass, and TeXAs and TeX are tellurium-based chalcogenide glasses. (After [43.7])

are globally associated with glassy materials. Further, an emphasis is placed on the unique advantages (lower processing temperatures, higher refractive index contrast, active functionality, etc.) enabled by some glass systems.

With these goals in mind, the chapter is organized as follows. In Sect. 43.1, we highlight the main advantages of glasses for photonic integration. These attributes include the unique processing options afforded by the existence of the glass transition and by the metastability of glasses. Section 43.2 provides an overview of the most-studied materials for glass-based integrated optics. This includes the standard glass formers (oxide, halide, chalcogenide glasses) as well as several materials that are generally classified as ceramics (Si_3N_4 , Al_2O_3 , etc.) but which can be realized as amorphous thin films. In Sect. 43.3, some unique advantages of glasses for realization of integrated light sources are reviewed. Section 43.4 provides a summary and some thoughts on future prospects for glasses in photonic integration.

43.1 Main Attributes of Glasses as Photonic Materials

The essential characteristic of a glass is the existence of a glass transition temperature (T_g). In short, if a viscous liquid is cooled fast enough, the liquid passes through the freezing temperature of the material with-

out making a phase transition to the solid crystalline state (see Fig. 43.2). Rather, it becomes a supercooled liquid, whose rate of change of specific volume (or enthalpy) with decreasing temperature remains constant

Fig. 43.2 Schematic plot illustrating the change in specific volume of a glass with temperature (after [43.11])

and equivalent to that of the molten liquid. At T_g , the slope of these curves (for example, specific volume versus temperature) changes abruptly (but in a continuous way) to a value that is approximately that of the corresponding crystal. Below T_g , the material is an amorphous solid or glass.

While glass forming has been a staple of human technological innovation for thousands of years, the physical processes underlying the glass transition are still a matter of some debate [43.11–13]. Several empirical facts are well known, however. The glass transition temperature of a particular material is not a constant, but is somewhat dependent on processing details such as the rate of cooling from the melt, or more generally on the technique used to form the glass (melt quenching, thin film deposition, etc.) and even the age of the glass [43.14]. T_g is slightly higher for a faster rate of cooling from a melt, for example, but in general $T_g \approx 2T_m/3$, where T_m is the melting/freezing temperature of the material [43.12]. For glasses that cannot be formed easily by melt quenching, such as amorphous Si [43.13], the direct experimental determination of T_g is not always possible, and indirect methods are sometimes used to estimate an effective T_g .

Central to the technological application of glasses is the ability to control their viscosity by way of temperature [43.5]. For stable glass formers, it is possible to

transition between states of very low viscosity (molten liquid), low viscosity (supercooled liquid), and high viscosity (frozen liquid; i.e. glass). This remarkable variation in mechanical properties with temperature, spanning several orders of magnitude in viscosity, underpins both the ancient and modern manufacture of glass products (by molding, extrusion, float processes, etc.). It is interesting to note that T_g can be defined as the approximate temperature at which the shear viscosity attains 10^{12} Pa s. Further, viscosity varies rapidly in the vicinity of T_g . For so-called strong glass formers (such as SiO_2), the viscosity η varies according to an Arrhenius equation of the form $\eta = A \exp(B/k_B T)$, where A and B are temperature-independent constants and k_B is the Boltzmann constant [43.12]. To form glasses into desired shapes, the temperature is typically controlled such that the viscosity is in the 10^2 to 10^7 Pas range, depending on the process and the stability of the particular glass composition [43.6, 15].

It was once held that only certain materials could form glasses, but it is now believed that the glassy state is attainable for all types of materials [43.11]. Accordingly, the literature contains references to various families of glasses, including inorganic (ceramic), organic (polymeric), and metallic glasses.

43.1.1 The Glass Transition as Enabler

The surface tension of liquids is a well-known enabler of optical quality surfaces [43.16]. Glass devices can be formed in the liquid state, and can thus accommodate manufacturing processes that are assisted by surface tension mediated self-assembly. The manufacture of modern single mode fibers is a good example of the enabling nature of the glass transition. In a typical process [43.4, 6, 17], highly purified glass layers are deposited either on the inside walls of a fused silica tube by chemical vapor deposition (CVD) or on the outside surface of a ceramic rod by flame hydrolysis deposition (FHD). The hollow glass cylinder (after removal of the ceramic rod in the latter case) is then heated (sintered) to $\approx 1600^\circ\text{C}$, such that it collapses to form a solid glass preform (typically 1 m in length and 2 cm in diameter). 1600°C is the approximate softening point of silica glass, typically defined as corresponding to a viscosity of $\approx 10^7$ Pas [43.6]. The fiber drawing process involves local heating of the preform to a temperature of approximately 2000°C (corresponding to a viscosity of $\approx 10^5$ Pa s). Thus, viscosity control is critical at nearly all stages of the process. Further, the drawing process allows tremendous control over the optical and

geometrical properties of the fiber, in part due to the self-regulating properties of surface tension effects in the supercooled liquid. As an added benefit, inhomogeneities in the original preform tend to be averaged out in the process [43.18]. The amazing properties of silica fibers (tensile strength comparable to that of steel, low loss, and extremely tight tolerances for material and geometrical parameters) are well known, and attest to the technological versatility of (silica) glasses. It is also interesting to note that the standard technique for splicing sections of silica fibers together, which is achieved with less than 0.1 dB loss [43.5], is based on a reflow process wherein surface tension contributes to their alignment.

Within integrated optics, the manufacture and optimization of PLC devices relies directly on the glass transition in many cases [43.9, 10]. PLC devices are manufactured in doped SiO₂ glasses deposited (by CVD, FHD, or sol-gel techniques) on a silicon wafer. The undercladding is often pure SiO₂, which can be formed by thermal oxidation of the silicon wafer. Typically, dopants in the core and uppercladding layers act to modify both the refractive index and the thermo-mechanical properties of the glass. In particular, controlled reflow (by heating the glasses near T_g) of these layers often plays an important part in the process. Reflow is used to consolidate the interface between layers, to smoothen the rough sidewalls of the waveguide core (formed by dry etching processes), and to assist in gap filling and planarization of the cladding layer over the patterned core layer [43.9], [43.18–20]. Typically, the layers are doped such that the glass transition decreases in the upward direction. In that way, a layer can be reflowed without affecting the underlying layers. As an example, a ‘pinned based reflow’ is shown in Fig. 43.3 [43.19]. The circle-section shaped core arises from selective reflow of the core material while its interface with the undercladding glass remains fixed. The upper boundary of the core is shaped by surface tension.

Surface tension driven manufacture of more exotic optical components has been widely studied. Examples include silica-glass based optical microcavities [43.21–23], nm-scale silica wires [43.24], photonic crystal fibers [43.25], microball lenses [43.26], and microlenses [43.27, 28]. In these cases, the reduction of scattering losses by surface tension mediated smoothening of interfaces is particularly important.

As discussed further in Sect. 43.2, high index contrast waveguides, photonic crystals, and microcavities are major themes within integrated optics. High index contrast (between the core and cladding of a waveguide, for example) is desirable because it enables strong con-

Fig. 43.3 A glass waveguide core is shown before (*left*) and after (*right*) a selective reflow process (From [43.19])

finement of light to small waveguides or small resonant cavities. This is essential to the realization of high-density integrated optics [43.9]. The downside of high index contrast is that scattering at interfaces increases with index contrast. This is clarified by the so-called Tien model for waveguide loss due to interfacial scattering in a symmetric slab waveguide [43.29]:

$$\alpha_S = \frac{2\sigma^2 k_0^2 h}{\beta} \Delta n^2 E_S^2 \quad (43.1)$$

where σ is the standard deviation (characteristic amplitude) of the roughness, k_0 is the free-space wavenumber, h is the inverse of the penetration depth of the mode into the cladding, β is the propagation constant of the mode, and E_S is the normalized electric field amplitude at the core-cladding interface. Further, $\Delta n^2 = n_{\text{core}}^2 - n_{\text{clad}}^2$, where n_{core} and n_{clad} are the core and cladding refractive indices, respectively. This equation explicitly shows the strong dependence of scattering loss on index contrast. A more accurate expression, derived by considering the statistics of roughness (not just the amplitude), is the Payne-Lacey model [43.30]:

$$\alpha_S = 4.34 \frac{\sigma^2}{k_0 \sqrt{2} d^4 n_{\text{core}}} \cdot g \cdot f \quad (43.2)$$

where d is the core thickness, g is a function that depends mainly on the core-cladding index offset, and f is a function that depends on the statistics of the roughness. If $r(z)$ is the random function describing the line-edge roughness (i.e. the deviation of the core-cladding interface from a straight line), the autocorrelation of $r(z)$ is often well described by an exponential function [43.31]:

$$R(u) = \langle r(z)r(z+u) \rangle \approx \sigma^2 \exp\left(\frac{-|u|}{L_c}\right) \quad (43.3)$$

where L_c is the so-called correlation length. It can be shown that for waveguide geometries of typical interest, low scattering loss requires both σ and L_c to be low. As a second illustration of the impact of interface roughness, it can be shown that the surface scattering limited quality (Q) factor for whispering gallery modes in a spherical

microsphere is approximately [43.23]:

$$Q_{ss} = \frac{\lambda^2 D}{2\pi^2 \sigma^2 L_c} \quad (43.4)$$

where D is the microsphere diameter. Again, minimization of scattering losses is correlated with minimization of σ and L_c .

It is interesting to compare recent results for high index contrast structures in crystalline materials and glasses. Much of the work on very highly confining waveguides and photonic crystals has focused on semiconductor material systems, especially the silicon-on-insulator (SOI) system [43.29, 30] and III-V semiconductor systems [43.33]. Generally, structures are defined by electron-beam or photolithography, followed by a dry etching process. Each of these steps has limited precision and contributes to the overall roughness [43.31]. With use of sophisticated processes, roughness parameters are typically on the order of $\sigma \approx 5$ nm and $L_c \approx 50$ nm, resulting in losses on the order of 3–10 dB/cm for sub-micron strip waveguides [43.30]. Significant improvement in these numbers is mostly reliant on advancements in lithography or etching processes. These same issues limit the performance of other high index contrast structures formed in semiconductors. For example the Q factor of semiconductor microdisk and microring resonators typically does not exceed 10^5 [43.34], and the loss of photonic crystal defect waveguides in semiconductors remains impractically large [43.35].

By comparison, glasses (at least certain glasses) offer the potential for much smaller characteristic roughness. If a glass is formed from a supercooled liquid state, surface tension effects can produce glass surfaces with nearly atomic level smoothness. The roughness of a melt-formed or reflowed glass surface is determined by surface capillary waves, which are small amplitude fluctuations at a liquid surface that become frozen in place at T_g [43.25]. The resulting RMS roughness is approximately given by [43.36]:

$$\sigma \approx \sqrt{\frac{k_B T_g}{\gamma(T_g)}} \quad (43.5)$$

where $\gamma(T_g)$ is the surface tension of the supercooled liquid at T_g . For silica glass, this equation predicts rms roughness on the order of 0.1 nm or less, and the correlation length of this inherent roughness is estimated to be as small as 3 nm [43.23]. Note that glasses with lower T_g and/or higher surface tension can in theory exhibit even lower values of surface roughness. Interestingly, sub-nm surface roughness has been experimentally verified

Fig. 43.4 (a) A submicron silica glass wire with sub-nm surface roughness is shown [43.24]. (b) A silica glass toroid sitting atop a silicon post is shown. The atomic-level smoothness of the toroid surface was achieved using a selective reflow process. (After [43.32])

for both melt-formed and fractured surfaces of silica glass [43.36] and indirectly from loss measurements in photonic crystal fibers [43.25]. Sub-nm roughness has also been determined for wet-etched surfaces of SiO_2 glass [43.37] and is not untypical for glass films deposited by evaporation.

The smoothness of glass surfaces has important implications for realization of low loss microphotonic devices, as evidenced by several recently reported results. While little work has been conducted on small core, high index contrast planar waveguides in glass, a method for fabricating sub-micron silica wires was recently reported [43.24] (see Fig. 43.4a). The authors estimated the rms surface roughness of their wires to be less than 0.5 nm, and demonstrated losses on the order of 1 dB/cm at 633 nm for 400 nm diameter wires. Sub-nm surface roughness has also been measured in the case of sol-gel glass microlenses formed by a reflow process [43.27]. Silica glass based microsphere cavities, typically formed by melting the end of fused silica fiber, exhibit Q factors of nearly 10^{10} [43.22, 23], the highest for any solid state microcavity. Recently, this concept

has been extended [43.21, 32] to the manufacture of silica toroid microresonators on a silicon substrate (see Fig. 43.4b). The latter devices exhibit Q factors exceeding 10^8 . Finally, glass-based photonic crystal fibers have been demonstrated to exhibit scattering loss near fundamental limits set by surface capillary waves [43.25]. This last result contrasts with the situation mentioned above for semiconductor photonic crystals, which to date are significantly compromised by optical scattering.

In summary, processing enabled by the glass transition clearly offers unique benefits for manufacture of microphotonic structures. It is necessary to add a caveat to this discussion, however. Many amorphous materials are conditional glass formers, and do not offer the full range of processing advantages outlined above. As an extreme example, amorphous silicon films typically crystallize at temperatures well below their effective glass transition temperature [43.13], and are not amenable to reflow processes. To varying degrees, this is true of many ‘glassy’ films used in integrated optics, such as silicon oxynitride and alumina. Further, the tendency towards crystallization varies greatly even amongst the traditional glass formers, as discussed below. Thus, chalcogenide and fluoride glasses will not generally support the range of viscosity control that enabled many of the SiO_2 -based devices mentioned. Having said that, novel techniques can sometimes circumvent crystallization problems. For example, pressure can be used as a tool for forming glass devices at temperatures below the onset of severe crystallization (but high enough to enable the glass to flow). Chalcogenide glass based lenses molded by the application of pressure and temperature are now commercially available [43.38]. Another interesting example is the recent work on extruded channel waveguides reported by Mairaj et al. [43.39]. Finally, much research has been directed at the fabrication of microphotonic elements in organic glasses by hot embossing [43.8]. In this technique, a hard master (such as a silicon wafer) is pre-patterned with the negative image of the desired photonic circuitry. The glass is heated above T_g and the master is pressed against the glass such that the image of its pattern is transferred to the softened glass. While studied mainly in polymer, this technique might also be applicable to low cost fabrication of photonic structures in ‘soft’ inorganic glasses.

43.1.2 Metastability

A glass is a metastable material, having been frozen as an amorphous solid possessing excess internal en-

ergy relative to the corresponding crystal. Metastability is a double-edged sword. On the one hand, it presents technological limitations with respect to the processing and use of a glass device. As an example, it is well known that commercial introduction of organic glass (polymer) based optical devices has been hindered by poor stability of many polymers at elevated temperatures or under exposure to high intensity light. On the other hand, metastability offers unique options for fabrication and optimization of photonic microstructures. Specifically, glass properties (optical, mechanical, chemical) can often be tailored or adjusted by the careful addition of energy, in the form of heat, light, electron beams, or ion beams. An example is provided by the commercially important fiber Bragg gratings (FBG), wherein UV light is used to induce a stable refractive index change in the Ge-doped core of a standard SiO_2 -based fiber. In the following subsections, the implications of metastability for glass-based integrated photonics are discussed.

Devitrification

Well below its glass transition temperature, a glass sits in a local energy minimum and is impeded by its own viscosity from reaching the lower energy crystalline state. A frequently cited example is that of silicate glass windows in ancient buildings, which have not exhibited any significant crystallization. However, addition of sufficient energy (such as heating a glass to some temperature above T_g) can result in crystallization of a glass. Controlled crystallization is a technologically useful means of modifying the mechanical, thermal, or optical properties of a glass, used in the production of glass-ceramics. However, devitrification produces a polycrystalline material, increases optical scattering loss, and is usually a problem to be avoided in manufacture of photonic devices.

As mentioned in Sect. 43.1.1, crystallization tendencies vary widely between various glass systems. The difference between the onset temperature for crystallization and T_g , $\Delta T = T_x - T_g$, is one of the parameters that define the stability of a particular glass. The high stability against devitrification of silicate glasses is one of numerous reasons that they have traditionally dominated glass technology. This stability underlies the manufacture of the structures discussed in Sect. 43.1.1. Other glass forming systems have lower stability against devitrification, often making their technological application a greater challenge [43.39, 40]. For example, a major research thrust in the field of fluoride and chalcogenide glass fibers is the identification of new compositions that

exhibit improved stability against crystallization during the fiber drawing process [43.41].

For integrated optics, this form of stability is not always so critical. Amorphous thin films created by chemical vapor deposition, sputtering, evaporation, etc. can often be processed at temperatures below the onset of any significant crystallization. This enables the use of conditional glass formers, such as Si_3N_4 , Al_2O_3 and semiconductors, in their amorphous state. However, it is interesting to review the early development of integrated optics, much of it focused on the identification of suitable thin film materials. Studies [43.43–45] that compared waveguide fabrication in polycrystalline (ZnO , ZnS , Al_2O_3 , etc.) and amorphous (Ta_2O_5 , polymer, sputtered glass) thin films showed that losses were orders of magnitude higher for the polycrystalline films. The lowest losses were initially obtained for polymer films [43.44], attributed to their amorphous structure and the smoothness of surfaces arising from spin casting of films.

If present, uncontrolled crystallization within films can be a dominant source of propagation loss [43.46]. For conditional glass formers, such as Al_2O_3 and TiO_2 , crystallite formation must be carefully avoided during the deposition process [43.47]. While less of an issue for natural glass formers, the possibility for crystallization must always be considered when a glass film is subjected to high temperature processing steps.

Structural Relaxation

Having been frozen in some metastable configuration at the time of formation, an amorphous solid will always be subject to some degree of aging (changes in the material properties on some time scale). At temperatures below T_g , the glass is usually inhibited from crystallization by a significant internal energy barrier. However, subtler changes in the network structure can occur, such as the transition from the initial state to a more stable (but still amorphous) second state. This so-called structural relaxation is manifested in many ways – experiments often probe the change in time of specific volume, structural signatures (such as by Raman spectroscopy), or optical properties of the glass. The rate of structural relaxation is highly dependent on temperature, being relatively fast at temperatures near T_g and significantly slower for temperatures far below T_g [43.13]. In fact, annealing of glasses at a temperature near T_g is a standard technique used to promote rapid structural relaxation and lessen the dependence of material properties on the processing history [43.6]. In many cases, this annealing step is not practical, and structural relaxation over the in-use lifetime of a glass-based device must be considered.

As the following discussion will illustrate, the rate of structural relaxation at temperature T_1 exhibits a logarithmic dependence on the temperature difference $T_g - T_1$. Thus, T_g is an important parameter in character-

Fig. 43.5 (a) A plot of the structural relaxation rate parameter versus the supercooling temperature for a wide range of organic glasses is shown. (b) The predicted change in refractive index versus time for an organic glass, with the rate constant β as a parameter. (After [43.42])

izing the long-term stability of a glass component. For example, SiO_2 has a very high T_g ($\approx 1100^\circ\text{C}$) and does not exhibit significant relaxation at room temperature, either on the time scale of typical experiments or over the typical lifetimes envisioned for glass devices. In fact, aging effects in silica fibers are predominately associated with the growth of defects formed in the glass at the time of manufacture. Environmental moisture is a particular contributor to this aging process. On the other extreme, structural relaxation in low T_g organic glasses is known to be an issue, and intrinsic aging effects in polymers have been widely studied [43.48]. In particular, low T_g glasses exhibit densification with time (relaxation of their specific volume) and a corresponding change in their refractive index. This is a particular concern for interferometric optical devices (gratings, resonators, Mach–Zehnder interferometers), which necessitate tight control of material indices.

Volume relaxation can be characterized by a rate parameter β , defined as:

$$\beta = \frac{1}{V} \left[\frac{\partial V}{\partial (\log t)} \right]_{P,T} \quad (43.6)$$

where V is volume, t is time, P is pressure, and T is temperature. Using the Lorentz–Lorenz expression, the following relationship has been derived from (43.6) [43.42]:

$$\left[\frac{\partial n}{\partial (\log t)} \right]_{P,T} = \frac{-\beta \left(\frac{\partial n}{\partial T} \right)_{P,T}}{\alpha} \quad (43.7)$$

where n is refractive index, $\partial n / \partial T$ is the thermo-optic coefficient, and α is the volume coefficient of thermal expansion. Zhang et al. [43.42] further showed that, for polymers, β is approximately a universal function of $T_g - T_1$ as shown in Fig. 43.5. This implies that the time rate of change of refractive index due to structural relaxation is strongly correlated with the parameter $\Delta T_{SC} = T_g - T_1$, termed the supercooling temperature. They also assessed the implications for polymer-based telecommunications devices, concluding that T_g needs to be higher than 300°C for many applications. This result provides a nice illustration of the impact of T_g on device stability.

While it is not necessarily reasonable to extend the foregoing results directly to inorganic glasses, the essential features of structural relaxation will be similar. The chalcogenide glasses in particular are sometimes called inorganic polymers, partly because of their softness and mechanical flexibility relative to silica-based glasses. Further, the range of T_g for chalcogenide glasses

(≈ 50 – 550°C) is similar to that of organic polymers, and studies on chalcogenide glasses [43.14] support the conclusion that structural relaxation would present similar restrictions on inorganic and organic glasses. Thus, lifetime restrictions due to relaxation should be considered in the application of any glass having relatively low T_g , including chalcogenide glasses, fluoride glasses, and many non-silicate oxide glasses [43.6].

Both the processing temperatures (during manufacture) and the in-use temperatures are important considerations in assessing the stability of a glass. Telecommunication devices are typically designed to withstand in-use temperatures between -40°C and 85°C [43.49]. As an example of a more demanding application, it has been proposed that glasses are good candidates for fabrication of integrated photonic elements on future integrated circuit chips [43.50]. In-use temperatures on modern microprocessors can reach 100 – 200°C .

Finally, it should be noted that any energy applied to the glass (light, electron beams, etc.) might induce structural relaxation. This has been most widely studied for the chalcogenide glasses, which exhibit a wide array of photoinduced structural changes [43.51]. A fascinating example is the so-called photoinduced fluidity phenomenon [43.52], in which intense sub-bandgap light can reduce the viscosity of a chalcogenide glass by several orders of magnitude (causing the glass to flow or melt). This effect is completely athermal, and in fact is often enhanced at low temperatures. While an extreme example, it illustrates the possibility of aging effects due to non-thermal processes in glass devices. For photonic devices, the main concern is usually the effect of light exposure over the in-use lifetime.

Metastability as Enabler

One highly desirable implication of metastability is the possibility for direct patterning of photonic structures in glasses using energetic beams (electron beams, ion beams, light). These effects can also be exploited for post-fabrication trimming of devices [43.53], which is important since many optical components have tolerances beyond the capabilities of practical fabrication processes.

Beam induced effects in glasses are generally linked to their random network structure. That is, unlike crystals, glasses contain a range of internal ‘defects’ – wrong bonds, dangling (missing) bonds, impurity atoms that act as network modifiers, as well as their inherent variation in bond angles. Addition of energy can cause a glass to undergo a transition from one metastable state to another. This transition is often accompanied by a change in the

Fig. 43.6 (a) A directional coupler is shown, as written in a multicomponent silicate glass by an ultrafast Ti:sapphire laser [43.54]. The black arrow indicates the coupling region. (b) Microscope image of a rib waveguide formed by direct exposure of a chalcogenide glass (As₂Se₃) in a UV mask aligner, followed by wet etching [43.55]

density of defects or by a structural change – rearrangement or reorientation of bonds. Associated with these structural changes are changes in the physical, chemical, and optical properties of the glass. Most existing knowledge about these induced structural changes is of an empirical nature, whereas the underlying physical mechanisms are still the subject of research.

The ability to induce transitions between metastable states is probably a universal property of amorphous matter. Perhaps for practical reasons, such as the availability of light sources of suitable wavelength, metastability was initially studied in amorphous semiconductors and low band gap chalcogenide glasses. It should be added, though, that chalcogenide glasses seem to be unique with respect to the variety of induced structural changes they exhibit or at least the magnitude of those changes [43.51]. This might be related to the relatively weak, highly polarizable covalent bonds that are characteristic of chalcogenide glasses. Nevertheless, the later discovery [43.56] of photoinduced refractive index changes in Ge-doped silica glass prompted a huge research and development effort because of the technological importance of silicate glasses. The main outcome of this work was the fiber Bragg grating (FBG), which is a critical component in modern telecommunications and sensing networks. FBGs are manufactured by inducing a quasi-permanent index change within the Ge-doped core of a standard silica fiber, by exposure to an UV laser beam. Writing wavelengths are in the 150 to 350 nm range, corresponding to photon energies below the nominal bandgap of SiO₂. The mechanisms underlying the index increase are still debated [43.9, 56]. However, it is believed that contributing factors are absorption by defects in the glass

(possibly generating further defects) and densification due to some sort of structural relaxation [43.57]. Typical index changes for standard fiber cores are in the 10⁻⁴ to 10⁻³ range, but several techniques (addition of other dopants, hydrogen-loading, etc.) have been developed to enable changes as high as 10⁻². Given the discussion in the preceding section, it is reasonable to ask whether photoinduced changes are themselves stable. The answer, in some cases, seems to be yes. Researchers have concluded that fiber Bragg gratings can have an operational lifetime of greater than 20 years, even at elevated temperatures of 80 °C [43.58].

Photosensitivity has been widely explored as a means to directly pattern integrated optics devices, especially in silica-based glasses [43.59]. In general, direct patterning is induced using photon energies close to the nominal bandgap energy of the glass or using intense light of lower photon energy [43.57]. In the latter case, photoinduced effects arise from nonlinear effects such as multi-photon absorption. In particular, the widely available Ti:sapphire laser has been applied to the writing of microstructures in a variety of glasses [43.54]. Because of the nonlinear nature of the writing process, writing with sub-band gap light allows the direct patterning of 3-dimensional structures (see Fig. 43.6).

Photosensitivity has been demonstrated within all of the standard glass families, and in many other amorphous thin films (see Sect. 43.2). Because of their large photosensitivity, direct patterning of integrated optics structures in chalcogenide glasses is possible using low power light sources [43.55, 60].

43.1.3 Glass as Host Material

For completeness, it should be mentioned that glasses are unique in their ability to incorporate a wide range of dopants, sometimes in very high concentration. This is related to the random network structure of a glass. Foreign species are much more likely to find a suitable bonding site, or simply space to reside, inside a glass versus a crystal. These foreign species can be rare-earth ions, transition metal ions, or semiconductor or metal nanoparticles, for example. As a result, a glass provides significant scope for active functionality. We can transform a passive glass into a laser glass, a nonlinear optical glass, or a magneto-optic glass, for example, by appropriate doping [43.3, 6].

43.2 Glasses for Integrated Optics

In general, thin films can be amorphous, polycrystalline, or crystalline. *Tien* and *Ballman* [43.45] provided an early review of waveguide results achieved for various materials lying within each of these categories. Unless the crystal grain size is sufficiently small relative to the wavelength of interest [43.47], polycrystalline films are too lossy for integrated optics. It should be noted that high attenuation might be tolerable if circuit length is sufficiently short. The present discussion is concerned with amorphous films, which *Tien* further subcategorized as low index ($n < 1.7$), medium index ($n < 2$), and high index ($n > 2$). For convenience, we will follow a similar approach in the following sections. This categorization is somewhat arbitrary, especially when considering material systems (such as the silicon oxynitride system) that enable a range of refractive index. It is interesting to note that 1.7 is the approximate upper limit for the refractive index of organic glasses [43.49]

As noted in Sect. 43.1, increased circuit density is one of the primary goals of integrated optics research [43.9]. Whether employing traditional total internal reflection effects or photonic band gap materials, increased density relies on high index contrast between at least two compatible materials. Note that the terminology ‘high index’ and ‘high index contrast’ are rather imprecise. For example, in silica PLC technologies core-cladding index differences of $\Delta n \approx 0.02$ have been labeled as ‘superhigh’ index contrast [43.10]. This is a very small value, however, relative to the index contrasts that characterize SOI photonic wire waveguides [43.30].

43.2.1 Low Index Glassy Films

SiO₂-Based Glasses

As mentioned in the introduction, the SiO₂ on silicon PLC system is the most widely used and developed glass-based integrated optics platform. PLC development (mainly in the 1990s) was driven by fiber optic long haul communication systems, especially the emergence of wavelength division multiplexing (WDM). Various devices, but especially arrayed waveguide grating (AWG) wavelength demultiplexers, were developed to a very high degree of sophistication by the telecommunications industry. Good early [43.18] and recent [43.9,10] reviews are available in the literature. A brief overview of the technology is given below, as it illustrates some of the advantages and challenges associated with glass-based photonic integration.

As mentioned in Sect. 43.1.1, commercial PLC waveguides are fabricated primarily by FHD [43.10] or by CVD [43.9]. In addition, considerable research has been conducted on sol-gel synthesis [43.61], with the aim of reducing fabrication costs and providing greater flexibility over the choice of glass compositions. Typically, the undercladding is pure silica glass. To raise its refractive index, the core layer is doped with Ge or P. Ge-doped SiO₂ is known for its photosensitivity, as discussed in Sect. 43.1.2. Addition of P lowers the viscosity and characteristic reflow temperature, enabling the processing options discussed in Sect. 43.1.1. Typical relative index offset Δ between the core and cladding is in the 0.3 to 2% range, corresponding to minimum waveguide bend radius R in the 2 to 25 mm range [43.10]. After RIE to form an approximately square waveguide core, an upper cladding is deposited and subjected to heat treatment. The upper cladding is often a boro-phosphosilicate glass (BPSG), partly to enable reflow. Further, the B and P dopants have opposite effects on refractive index allowing a nearly symmetric waveguide structure to be obtained.

Given the target applications, it is not surprising that PLC technology placed a great emphasis on efficient coupling between the integrated waveguides and external fiber waveguides. Thus, waveguide cross-sectional dimensions and refractive index contrast between core and cladding layers were tailored to provide a good impedance match (low reflection and good modal overlap) to standard fiber. By employing essentially the same glass (doped SiO₂) as that used to construct fiber, it is even possible to achieve intimate reflowed (fusion type) coupling between the integrated and fiber guides [43.18]. The emphasis on impedance matching is due to the great importance of minimizing insertion loss in fiber systems, but presents some practical limitations:

1. The relatively low index contrast ($\approx 10^{-3}$) between core and cladding necessitates thick glass films. For example the undercladding or buffer layer, often a thermally grown SiO₂ layer, must typically exceed 12 μm in order to negate radiation losses into the high index silicon substrate. Further, high temperature anneals (typically 900–1150 °C) are required to drive out hydrogen impurities and to reflow the core and upper cladding layers. The combination of thick films, high temperature anneals, and thermal expansion mismatch can result in wafer bending and damage to the glass films. This is partly alleviated

in practice by depositing identical layers on both sides of the Si wafer [43.9], which adds cost and complexity.

2. Since modal area and minimum bend radius scale inversely with core-cladding index contrast, traditional PLC waveguides do not support high-density optical integration. As mentioned above, index contrasts in the 0.3 to 2% range correspond approximately to bending radii in the 25 to 2 mm range [43.10].

In recent work at Corning [43.62], very low loss (< 0.1 dB/cm) waveguides and ring resonators were realized in PECVD grown silica-germania waveguides having index contrast as high as 4%. Such high index contrasts can accommodate bending radius of less than 1 mm, which is comparable to the range explored recently by IBM researchers using silicon oxynitride materials [43.63].

Amorphous Aluminium Oxide

Sapphire (crystalline Al_2O_3) is amongst the most important solid-state laser hosts. Alumina (polycrystalline or amorphous Al_2O_3) is an important industrial material in its own right, possessing outstanding mechanical and thermal properties [43.15]. Amorphous Al_2O_3 films are of interest for integrated optics for several reasons [43.47]. First, the refractive index is relatively high (although falling within the low index range specified above), typically $n \approx 1.65$. Second, Al_2O_3 is an excellent host for rare earth and transition metal dopants. As discussed in Sect. 43.3, rare earth dopants of interest are typically trivalent, matching the valency of Al ions in Al_2O_3 [43.64]. As a result, rare earth ions can be incorporated easily into the alumina matrix. In short, Al_2O_3 can homogeneously dissolve large concentrations of rare earth ions and is therefore of interest for realization of integrated amplifiers and light sources. Finally, Al_2O_3 films typically have excellent transparency from the UV to mid-IR range.

Fluoride Glasses

Heavy-metal fluoride glasses (typically fluorozirconate glasses) such as ZBLAN have been widely studied since their discovery in 1974 [43.41]. One of their outstanding attributes is a wide transparency range, extending from the UV well into the mid-IR (see Fig. 43.1). They have received considerable attention as fiber optic materials, because theory predicts a minimum absorption well below that of silica glass. Further, rare earth ions exhibit the greatest number of useful radiative transitions when embedded in fluoride glasses [43.65]. This is due to

their wide transparency window and low characteristic phonon energies (see Sect. 43.3).

Fluoride glasses typically have refractive indices in the 1.47–1.57 range, which is advantageous in terms of being well matched to silica glasses. Thin film deposition of these complex multicomponent glasses is difficult, and thermal expansion mismatches with standard substrates create further challenges. For these reasons, fluoride glasses have not been widely explored for applications in integrated optics. The so-called PZG fluoride glasses ($\text{PbF}_2 - \text{ZnF}_2 - \text{GaF}_3$) have been successfully deposited using straightforward evaporation techniques, enabling relatively low loss waveguides and erbium-doped amplifiers on a silicon platform [43.66].

43.2.2 Medium Index Glassy Films

Silicon Oxynitride

Silicon oxynitride (SiON) films are generally deposited by a CVD technique. The promise of this material system for integrated optics was identified in early work [43.45]. One of the main attributes of SiON is that it is a standard material system employed in silicon microelectronics, and the thin film technology has been developed accordingly [43.47, 63]. Because of this, SiON is currently being studied as potential material for on-chip interconnects [43.50]. Further, the system enables a continuous range of refractive index from approximately 1.45 (SiO_2) to 2 (Si_3N_4) at 1550 nm wavelength. This index range has been extended to approximately 2.2 by deposition of non-stoichiometric, silicon-rich nitride films [43.67]. SiON and SiN have been amongst the most explored materials for realization of microring resonator structures [43.53, 67].

As an optical material, SiON has some drawbacks. The main one is the presence of hydrogen impurities in films deposited by traditional techniques. Overtones due to hydrogen bonds (mainly N–H and O–H) can produce impractically large values of loss in the 1300 nm and 1550 nm telecommunications bands [43.62]. Long term, high temperature annealing (typically at $> 1000^\circ\text{C}$) is required to reduce this loss. Interestingly, structural relaxation on the time scale of hours and days has been observed in such annealed films [43.47]. Perhaps related to this metastability, UV light has been used as a means to trim the refractive index of SiN-based microring resonators [43.53]. Modified deposition processes that can produce SiON films having low stress and low hydrogen content (without requiring a high temperature annealing step) have been reported recently [43.63, 67]. However,

inherent film stress can limit the maximum thickness to a few hundred nanometers in some cases [43.50].

43.2.3 High Index Glassy Films

Amorphous Metaloxides

Many amorphous metaloxides (Y_2O_3 , Nb_2O_5 , Ta_2O_5 , etc.) have traditionally been used as high index layers in optical thin film stacks [43.49]. It is logical to look at these materials in the hunt for high index thin films for integrated optics. Often these oxides are miscible with SiO_2 , making it possible to tune the refractive index and other material properties over a range of values (as in the case of silicon oxynitride) [43.69].

TiO_2 films are used as dielectric layers, optical coatings, and to protect underlying materials from mechanical damage or corrosion [43.47]. The high dielectric constant of TiO_2 is widely exploited in microelectronics applications. It also has useful optical properties, including a refractive index as high as 2.6 (depending on film deposition details) and good transparency from the UV to mid-IR. The TiO_2 – SiO_2 material system has good properties for sol-gel synthesis of thin films [43.61]. Integrated waveguides based on TiO_2 have been studied [43.47, 69], and AWG devices in TiO_2 -rich oxide glass with $n \approx 1.9$ were recently reported [43.70].

Ta_2O_5 (With $n \approx 2.1$) is another well-studied material, used for example as a high dielectric constant material in microelectronics. It has low absorption in the visible to near infrared wavelength range, and has been recently studied as a material for active integrated optics [43.71, 72]. Further, $\text{Ta}_2\text{O}_5/\text{SiO}_2$ has been applied to the study of compact microring resonators [43.73].

TiO_2 and Ta_2O_5 have been used in the fabrication of three-dimensional photonic crystals with fundamental bandgaps in the visible and near infrared [43.68, 74]. An example is shown in Fig. 43.7.

Heavy Metal Oxide Glasses

These glasses are based primarily on the oxides of bismuth (Bi_2O_3) and lead (PbO). They have relatively low phonon energies and transmit further into the infrared than most oxide glasses [43.75]. They also have interesting magneto-optic [43.6] and nonlinear optical [43.3] properties.

Chalcogenide Glasses

Many chalcogenide alloys, based on S, Se, or Te, are excellent glass formers. In fact, Se is the only element able to easily form a glass on its own [43.14]. These

Fig. 43.7 A three-dimensional photonic crystal fabricated using the autocloning growth technique is shown. The *bright* and *dark* layers are TiO_2 and SiO_2 glass, respectively [43.68]

glasses are characterized by very low phonon energies, good transparency in the mid-infrared, and a wide array of beam-induced structural changes [43.51]. Further, chalcogenide glasses are essentially amorphous semiconductors, with electronic absorption edge typically in the visible to near infrared. Related to this, they have very high refractive indices, ranging from 2.2 for sulfide glasses to greater than 3 for some telluride glasses. They are currently of industrial interest for night-vision optics [43.38], fibers for infrared transmission [43.41], and optical and electronic memory elements [43.51].

Chalcogenide glasses have many appealing features for integrated optics. High quality thin films can often be deposited by straightforward techniques such as evaporation or sputtering. Their high indices make them suitable for realization of compact waveguides [43.55] and photonic crystals [43.76]. Their beam-induced properties enable many unique processing options. Some chalcogenide alloys have good potential as laser glasses [43.41], with the ability to uniformly dissolve large concentrations of rare-earth ions. Perhaps of greatest interest, the chalcogenide glasses are amongst the most promising materials for nonlinear integrated optics [43.77, 78]. On this last point, several chalcogenide glasses have ultrafast optical Kerr response 2 to 3 orders of magnitude higher than that of SiO_2 , while satisfying basic figure of merit criteria for all-optical switching. Results for metal-doped chalcogenide glasses [43.78] suggest even higher nonlinearities might be attainable. Combined with the possibility of realizing highly confining waveguides, this makes chalcogenide glasses one of few material systems that can realistically satisfy long-standing goals for nonlinear processing in integrated optical circuits. For example, it has been estimated [43.77]

that 1 pJ pulses of 1 ps duration (≈ 1 W peak power) could induce phase shifts (due to self phase modulation) greater than π in feasible chalcogenide glass waveguides with length on the order of a few centimeters. This is predicated on realization of low loss waveguides with modal area of $\approx 1 \mu\text{m}^2$. Recent experimental results suggest that this goal is within reach [43.55].

Tellurite Glasses

While TeO_2 is a conditional glass former, the addition of other oxides can result in stable glasses with

many interesting properties [43.75]. They typically have refractive index greater than 2, low phonon energy, large optical nonlinearities, and a high acousto-optic figure of merit. Further, they have been widely studied as hosts for rare-earth ions. Of particular interest has been the wide bandwidth of the 1550 nm emission exhibited by erbium in tellurite glass [43.79]. Because of these numerous attractive properties, tellurite glasses and amorphous TeO_2 films ($n \approx 2.2$) have received some attention for applications in integrated optics [43.80].

43.3 Laser Glasses for Integrated Light Sources

Active functionality includes means to generate and detect light (especially stimulated emission and absorption) and means to control (switch, modulate, etc.) light signals. Numerous material properties are employed in active photonics, including thermo-optic, acousto-optic, magneto-optic, electro-optic, and nonlinear Kerr effects. Many glasses have attractive thermo-optic or acousto-optic properties, and a few examples were cited in Sect. 43.2. Also in Sect. 43.2, some glasses with promising nonlinear optical properties were discussed. Elsewhere in this volume, K. Tanaka has provided an excellent review of nonlinearities in photonic glasses. A recent, thorough review of magneto-optic glasses is also available [43.6].

Arguably, the most critical element for photonic integration is an integrated light source. Rare-earth doped glasses are well-established laser media, used especially for the realization of bulk and fiber lasers. Considerable effort has been directed towards development of integrated amplifiers and lasers based on such glasses. In the following, we attempt to highlight some ways in which light sources based on glasses are uniquely enabling, relative to those based on crystalline materials. The performance advantages discussed below combined with the properties discussed in earlier sections (fabrication options) make glasses particularly attractive.

43.3.1 Advantages of Glass-based Light Sources

Stimulated emission devices in glass are almost always based on trivalent rare-earth dopants [43.6]. Thus, the term laser glass can usually be equated with the term rare-earth doped glass. Rare-earth doped laser glasses have been widely studied and reviewed [43.64, 65]. Fur-

ther, recent and comprehensive reviews on Nd- and Er-doped integrated glass amplifiers and lasers are available [43.6, 81]. Relative to single crystal hosts, glass hosts result in rare-earth ions exhibiting broadened luminescence lines and lower peak stimulated emission cross-sections [43.65]. This property is a result of the random network structure of glasses; embedded rare earth ions exist in a range of local environments. The broadened, weaker emission is of great importance for the realization of broadband, low noise fiber amplifiers.

It should be noted that the semiconductor injection laser is an extremely advanced technology, and is the dominant type of integrated light source at present and for the foreseeable future. Semiconductor lasers have important advantages over any glass-based device demonstrated to date. First, semiconductor gain media typically have gain coefficients of the order $\approx 100 \text{ cm}^{-1}$ [43.17]. By comparison, glasses require high rare-earth dopant concentration to achieve gain coefficients exceeding 1 cm^{-1} . Thus, semiconductor optical amplifiers (SOAs) and lasers have cavity lengths measured in tens to hundreds of μm while it is typical for glass waveguide amplifiers and lasers to be measured in cm. Second, semiconductor light sources are pumped electrically while glass devices are typically pumped optically. Electrical pumping is highly desirable for optoelectronic integration of photonic devices on electronic chips. However, as discussed below, integrated glass waveguide lasers have important advantages of their own [43.82].

The lifetime of the metastable lasing level in rare-earth doped glasses is usually on the order of ms, much longer than the ns lifetimes typical of semiconductor gain media. This long lifetime implies that the gain does not change rapidly with variations in input power (pump

or signal). This is an essential feature of the commercially important erbium-doped fiber amplifier (EDFA); the long lifetime (≈ 10 ms) of the $^4\text{I}_{13/2}$ level of erbium in silicate glass contributes to low noise operation, high pump efficiency, and low crosstalk between wavelength channels in a WDM system [43.83]. Further, since the relaxation oscillations in glass waveguide lasers occur at relatively low frequency, glass lasers can be modelocked at correspondingly much lower repetition rates compared to semiconductor lasers [43.82]. This can enable much higher peak intensities from the glass laser.

Related to the discussion in Sect. 43.1, lower cavity loss (higher cavity Q) is generally possible for glass devices. Further, the long metastable lifetime of the rare-earth transition allows glass lasers to have linewidths approaching the Schawlow–Townes limit [43.84]:

$$\Delta\nu = \frac{2\pi h\nu_0 (\Delta\nu_c)^2}{P} \left(\frac{N_2}{N_2 - N_1} \right) \quad (43.8)$$

where ν_0 is the laser center frequency, P is the laser output power, N_2 and N_1 are the population densities of the upper and lower lasing levels, and $\Delta\nu_c = (1/2\pi t_c)$ with t_c the photon lifetime in the cavity. The high Q of glass laser cavities coupled with relatively high output powers enables linewidths less than 10 kHz, orders of magnitude below that of semiconductor DFB lasers [43.82]. The high cavity Q and long metastable lifetime is also advantageous for achieving ultrastable passive mode locking, with low timing jitter and pulse-to-pulse power variation.

Finally, glasses offer the possibility of integration on various substrates. While semiconductor lasers are inherently integrated structures, they are not easily transportable between platforms. For example, III-V semiconductor lasers have not shown great promise (in spite of heroic efforts in some cases) to satisfy the desire for a compact, truly integrated light source on the silicon electronics platform. Glasses (perhaps doped with semiconductor nanocrystals) are increasingly viewed as the more promising route to achieving such a goal [43.64].

43.3.2 Alternative Glass Hosts

The theoretical maximum gain (cm^{-1}) of a rare-earth doped glass waveguide amplifier can be expressed [43.81] as $\gamma_p = \Gamma\sigma_p N_{\text{RE}}$, where σ_p is the peak (versus wavelength) stimulated emission cross-section (cm^2) for the transition of interest and N_{RE} is the volume density (cm^{-3}) of the rare-earth ions. Γ is a dimensionless factor (lying between 0 and 1) that accounts for the spatial overlap of the waveguide mode (at the wave-

length to be amplified) and the active ions producing the gain. It can be optimized through waveguide design, irrespective of the glass host, and will not be considered further here. The expression for γ_p neglects all waveguide losses (due to scattering, etc.) and assumes that all of the rare-earth ions have been promoted to the desired lasing level; i. e. a complete population inversion. It is therefore an ideal and unattainable limit, but is useful for framing the following discussion.

Since compactness is a central goal of integrated waveguide lasers, alternative glass hosts can be compared on the basis of the maximum gain (γ_{max}) that they enable in practice (for a given transition of a given rare-earth ion). Further, since low noise operation relies on a near complete population inversion [43.81], it is desirable that $\gamma_{\text{max}} \approx \gamma_p$. In simple terms, the glass should dissolve a large concentration of the rare earth ion (high N_{RE}), should result in a large stimulated emission cross-section for the desired transition, and should enable the realization of a nearly complete population inversion. The importance of other practical considerations, such as stability, processing options, and physical properties of the glass, will depend on the intended application. Some hosts provide unique advantages, such as flexible pumping options, as discussed in Sect. 43.3.3.

As mentioned, laser transitions in glasses are generally provided by radiative decay between two energy levels of a trivalent rare-earth ion. Perhaps the most important example is the $^4\text{I}_{13/2}$ to $^4\text{I}_{15/2}$ transition of Er^{3+} , which produces luminescence in the 1500–1600 nm wavelength range. Once an ion has been promoted (by pumping) to the upper lasing level, it will eventually transition to another state by interactions with the glass, impurities in the glass, the photon fields (at the signal or pump wavelength), or with other rare-earth ions in its vicinity [43.65]. The metastable lifetime of the upper lasing level can be expressed [43.81]

$$\frac{1}{\tau} = A + W_{\text{MP}} + W_{\text{ET}} + W_{\text{IMP}} \quad (43.9)$$

where A is the effective rate of spontaneous radiative decay to all lower lying levels, W_{MP} is the rate of non-radiative decay due to multi-phonon energy exchanges with the glass, W_{ET} is the rate of non-radiative energy transfer due to interactions between closely spaced rare-earth ions, and W_{IMP} is the rate of energy transfer to quenching impurity centers in the glass. The first three terms on the right will be discussed below. For the last term, a classic example is the quenching of the 1550 nm luminescence band of erbium due to resonant energy transfer to OH^- impurities in silica glass [43.65].

The choice of a particular glass host will impact several important properties of a given transition: pumping efficiency, peak gain, linewidth, metastable lifetime, etc. Alternative glasses can be compared on the basis of a few key parameters, as discussed in the following sub-sections. Representative data for erbium in various glasses is given in Table 43.1.

Stimulated Emission Cross-Section

Stimulated transitions of rare-earth ions in glass tend to be predominately driven by electric dipole interactions [43.65]. For a given transition of interest, the spontaneous emission probability can be expressed in cgs units as [43.6, 85]:

$$A = \frac{64\pi^4 e^2 \chi}{3h (2J+1) \lambda_p^3} S \quad (43.10)$$

where J is the total angular momentum of the upper lasing level, λ_p is the peak emission wavelength, and χ is the local field correction factor. For electric-dipole interactions of an ion in a dielectric medium, $\chi \approx n(n^2 + 2)^2/9$, with n the refractive index of the host glass. S is the quantum-mechanical line strength for the transition. Further, the peak stimulated emission cross-section can be expressed in terms of the spontaneous emission probability:

$$\sigma_p = \left(\frac{\lambda_p^4}{8\pi c n^2 \Delta\lambda_{\text{eff}}} \right) A \quad (43.11)$$

where $\Delta\lambda_{\text{eff}}$ is the effective linewidth of the transition. From (43.10) and (43.11), the host-dependent factors that influence σ_p are the refractive index, the line strength, the effective linewidth, and to a lesser extent the peak emission wavelength (which typically varies only slightly between different hosts). The local field correction factor is significant in hosts with large refractive

index, and can result in an enhancement of the stimulated emission cross-section and a reduction of the radiative lifetime. This is especially true for chalcogenide glass hosts, which typically have refractive index in the 2 to 3 range.

Metastable Lifetime

In the limit of low rare-earth dopant concentration, W_{ET} in (43.9) is zero because the ions are sufficiently well separated to negate their interaction. If the difference in energy between the upper lasing level and the adjacent state is several times the effective phonon energy, then W_{MP} can be neglected to first order. Further neglecting impurity quenching, we can then assert that $\tau_0 \approx 1/A$, where τ_0 is the metastable lifetime in the limit of low rare-earth concentration. From Einstein's relations, $A \approx \sigma_p$, so it follows that $\tau_0 \approx 1/\sigma_p$. In short, hosts that result in an enhancement of the peak stimulated emission cross-section (due to an enhancement of the electric-dipole interaction or because of a high local field correction factor) will also result in a reduction in metastable lifetime. In other words, both stimulated and spontaneous emission rates are enhanced.

The inverse scaling of stimulated emission cross-section and metastable lifetime represents a tradeoff, as it is generally desirable for the lifetime to be as large as possible. Some of the advantages of long lifetime were discussed in Sect. 43.3.1. In addition, the pumping efficiency (gain per applied pump power) of a waveguide amplifier scales directly with τ [43.6, 81] and, therefore, the threshold for CW lasing scales inversely with τ [43.86].

Concentration Quenching

Glasses differ greatly in the amount of a given rare-earth dopant that they are able to dissolve. To avoid problematic ion-ion interactions, the rare-earth ions should be

Table 43.1 Representative parameters for erbium ions embedded in various types of glass (after [43.61, 64, 65])

Glass host	Refractive index n	Peak stimulated emission cross-section σ_p (10^{-21} cm^2)	Metastable lifetime τ (ms)	Quenching concentration ρ_q (10^{20} cm^{-3})	Effective luminescence bandwidth (nm)
Silica	1.46	7	12	—	11
Amorphous Al_2O_3	1.64	6	7.8	—	55
Aluminosilicate	1.5	5.7	10	3.9–6.0	43
Phosphate	1.56	8	10	3.9–8.6	27
Fluoride	1.53	5	9	3.8–5.3	63
Tellurite	2.1	13	3.3	—	80
Sulfide	2.4	20	2.5	3.2	—

incorporated homogeneously into the glass structure. In the extreme case of high concentration, the rare-earth ions will form microscopic clusters (phase separation). Such clustering is highly detrimental, as typically all of the ions within a cluster are effectively removed from the desired stimulated emission process [43.81]. As is well known [43.64, 65], the onset of clustering occurs at quite small values (≈ 0.1 at %) in pure silica glass. The addition of Al_2O_3 to SiO_2 allows silica-based fibers to dissolve a significantly higher concentration. For example, a value of 10–20 for the Al ion to Er ion concentration ratio has been shown to greatly reduce clustering of Er ions in silica glass [43.86]. Interestingly, the addition of Ga (with similar ratio) to chalcogenide glasses has been shown to provide a similar reduction in rare-earth ion clustering [43.41]. These additives essentially modify the glass network, and create sites for isolated rare-earth ions to be incorporated. For similar reasons, multicomponent aluminosilicate and phosphosilicate glasses have been favored in the development of integrated waveguide amplifiers, where the rare-earth concentration must be orders of magnitude higher than in fibers [43.81].

Even in the absence of significant clustering, ion–ion interactions can occur at high concentrations. This is simply due to the reduction in inter-ion spacing, and is exacerbated by any non-uniform (non-homogeneous) distribution of the rare-earth ions in the glass host. These interactions are manifested by a reduction in the metastable lifetime, often well described by the semi-empirical expression [43.61, 65]:

$$\tau(\rho) = \frac{\tau_0}{1 + (\rho/\rho_Q)^p}$$

(43.12)

where ρ is the rare-earth ion concentration, ρ_Q is the so-called quenching concentration, and p is a fitting parameter ($p \approx 2$ for interactions between pairs of ions). The parameter ρ_Q is useful for comparing glasses in terms of their ability to uniformly dissolve a given ion.

Phonon Energies

The characteristic phonon energies of a glass depend on the weights of its constituent atoms and the strength and nature (ionic or covalent) of its bonds. Typical values are shown in Table 43.2. The rate of multi-phonon decay (WMP) between two energy levels depends exponentially on the number of phonons required to bridge the energy gap. Thus, the phonon energy has a great impact on the ultimate efficiency of a desired radiative transition. Low phonon energy can be a good or bad

thing, depending on the transition of interest and the particular pumping scheme.

Mid- to far-infrared transitions of rare-earth ions can exhibit reasonably high quantum efficiency in low phonon energy hosts, such as fluoride, tellurite, and especially chalcogenide glasses. If the same ions are embedded in silicate or phosphate glasses, these transitions are completely quenched by non-radiative processes at room temperature. For this reason, rare-earth doped chalcogenide glasses are of interest for realization of long wavelength amplifiers and lasers [43.41, 64]. Also unique to low phonon energy hosts is the possibility of efficient upconversion lasers [43.87]. In simple terms, the long lifetimes of numerous energy levels allows processes such as ion–ion interactions and excited state absorption (ESA) to efficiently populate the higher energy levels. By contrast, these levels are rapidly depopulated by phonons in oxide glasses. On the other hand, population of the higher levels is highly detrimental if the desired transition is between two lower levels. For example, the efficient pumping of EDFAs using 980 nm wavelength sources relies on the rapid decay (via multiphonon processes) of ions from the $^4\text{I}_{11/2}$ pumping level to the $^4\text{I}_{13/2}$ lasing level. In fluoride and chalcogenide glass hosts, ions raised above the $^4\text{I}_{11/2}$ level tend to become trapped in higher levels (so-called ‘population bottlenecking’ [43.65]). Cerium co-doping has been shown to alleviate this problem [43.66]. Another approach is addition of light elements to the glass network, to increase the phonon energy [43.79].

43.3.3 Progress Towards Integrated Light Sources in Glass

Per the preceding discussion, important goals for glass-based lasers include size reduction and the need for simplified optical or (ideally) electrical pumping

Table 43.2 Characteristic maximum phonon energies for a variety of glass hosts (after [43.6, 65])

Glass host	Phonon energy (cm ⁻¹)
Borate	1400
Phosphate	1200
Silicate	1100
Germanate	900
Tellurite	700
Heavy-metal fluoride	500
Chalcogenide (sulfide)	450
Chalcogenide (selenide)	350

Fig. 43.8 Spiral geometry demonstrated for Al_2O_3 -based waveguide amplifiers, where erbium was introduced by ion implantation (*left*) and co-sputtering (*right*). The bright green emission is a result of ion–ion interactions causing up-conversion for the co-sputtered sample [43.89]

schemes. It should be noted that integration brings its own advantages. As is well known, waveguide lasers have greatly enhanced pump efficiency (gain per applied pump power) relative to their bulk solid-state counterparts. This is due to the confinement of the pump beam and the stimulated emission beam within a small volume. As explored recently in [43.88], this benefit scales with confinement. Amplifiers based on very high index contrast waveguides can have extremely high pump efficiency, as well as requiring only a small amount of wafer real estate. Thus, while the gain per unit length is limited by concentration quenching in rare-earth doped glasses, devices can still be very compact through the use of folded spiral waveguide layouts as illustrated in Fig. 43.8 [43.89].

In terms of maximizing gain per unit length, phosphate glasses have produced the best results to date. This is due to their ability to uniformly dissolve large concentrations of rare-earth ions, and the high cross-sections exhibited by those ions. The high phonon energy can also be an advantage as discussed above. Phosphate glass disks (typically ≈ 1 mm thick) have been widely used for realization of compact microlasers [43.90] and ultrafast modelocked lasers with pulse length as short as 220 fs [43.91] and repetition rate exceed-

ing 40 GHz [43.92]. Phosphate glass fiber lasers with a length of only 7 cm have recently generated 9.3 W of output power [43.93]. Sputtered phosphate glass waveguides have produced gains exceeding 4 dB/cm [43.94]. More recently, a phosphate glass co-doped with 8 at % erbium and 12 at % ytterbium was used to realize ion-exchange waveguides exhibiting 4.1 dB gain in only 3 mm length [43.95]. At such high concentrations, the rare-earth constituents can hardly be called dopants as they exceed the concentration of some of the host glass constituents.

On the theme of simplified pumping options, so-called broadband sensitizers [43.96] are of great interest. A broadband sensitizer is essentially a co-dopant that is able to efficiently absorb pump energy over a wide wavelength range and subsequently excite nearby rare-earth ions to the desired lasing level. This might enable planar waveguide amplifiers that are pumped transversely using low cost broadband light sources [43.64]. Silicon nanoclusters (embedded in oxide glass) are receiving the most attention at present. In addition to acting as a broadband sensitizer, there is evidence that these nanoclusters can enhance the stimulated emission cross-section of co-doped rare-earth ions by 1–2 orders of magnitude. Han et al. [43.97] have reported a waveguide amplifier (on a silicon platform) exhibiting signal enhancement of 7 dB/cm, in spite of a very low erbium concentration. The same group has also reported gain using transverse pumping by LED arrays [43.98]. Finally, the presence of a large concentration of silicon clusters makes electrical pumping a realistic possibility for some silicon-rich oxide glasses [43.64].

It seems very likely that chip-scale glass-based lasers are on the verge of playing a central role in photonics. These lasers will deliver moderate power in a very small package, and will offer extreme spectral purity or stable, high-repetition rate pulses. They might even satisfy the long-standing desire for a silicon-based laser [43.64, 91], facilitating the convergence of photonics and electronics.

43.4 Summary

Glasses have numerous advantages (ease of component fabrication, low scattering loss, flexible atomic structure) that have made them the workhorse material for traditional bulk optics applications. These properties can provide equal or greater advantage in the realization of microphotonic devices and circuits. The glass transi-

tion can enable manufacturing techniques unavailable to other materials, and realization of devices having surface roughness approaching fundamental limits. Owing to this, glasses underlie the highest Q microcavities and some of the lowest loss photonic crystal and microphotonic waveguides reported to date. The metastability

of glass enables a rich array of processing and post-processing options. Direct patterning of waveguides, gratings, and other microphotonic elements by energetic beams is widely studied. These methods of material modification are also promising for post-fabrication trimming of devices. On the other hand, metastability has implications for processing and aging of glass devices.

Rare-earth doped glasses offer numerous advantages relative to other solid-state laser media, especially for realization of ultra-low noise single frequency and ultrafast lasers. Recent advances have greatly increased the maximum gain per unit length, and point to the potential for compact, on-chip glass-based light sources. Progress with respect to 2nd and 3rd order nonlinear effects in glasses is ongoing. It is expected that cm-scale switching or pulse shaping devices based on glasses will become feasible, at least for niche applications.

Overall, it is clear that glasses can contribute greatly to the development of compact, low-loss, multifunction optics integrated with electronics.

Defining Terms

Amorphous Metaloxides are glassy alloys of a transition metal with oxygen, typical examples being TiO_2 , Ta_2O_5 , Nb_2O_5 , and Y_2O_3 . In bulk form, these materials are typically polycrystalline or crystalline ceramics. However, amorphous thin films can be deposited with relative ease, and they have been widely used as high index layers in optical filter design and as dielectric layers in the microelectronics industry.

Broadband Sensitizer is typically some species co-doped along with rare-earth ions into a glass host, in order to increase the pumping efficiency or radiative efficiency of the rare-earth ions. Various sensitizers have been demonstrated, including silicon nanoclusters, silver ions, and other rare earth ions (such as in the sensitization of erbium by ytterbium).

Chalcogenide Glasses are amorphous alloys containing S, Se, and/or Te. Typical examples include Se, GeS_2 , GeSe_2 , As_2S_3 , As_2Se_3 , and As_2Te_3 . By intermixing these and other binary chalcogenide glasses, a wide variety of multicomponent glasses can be formed. Further, a wide range of non-stoichiometric compositions is possible. Several compositions have become standard industrial materials, including $\text{Ge}_{33}\text{As}_{12}\text{Se}_{55}$ and $\text{Ge}_{28}\text{Sb}_{12}\text{Se}_{60}$. The chalcogenide glasses are characterized by narrow bandgaps and good transparency in the mid to far infrared wavelength range.

Concentration Quenching refers to the reduction in luminescence efficiency and luminescence lifetime of a laser glass when the rare-earth dopant concentration is high. Quenching is due to interactions between closely spaced rare-earth ions at high concentrations. These interactions create new pathways, other than the desired radiative decay, for the ions to relax to the ground state after they have been raised to a desired lasing level by pump energy.

Devitrification refers to the transition of a glassy material to its lower energy crystalline state. This process is usually driven by thermal energy, such as if the material is held at some characteristic temperature above its glass transition temperature. The difference between the crystallization temperature and the glass transition temperature for a particular glass is one measure of its stability.

Fluoride Glasses are multicomponent glasses, typically based on fluorides of zirconium, barium, lead, gallium, lanthanum, aluminium, and sodium. They have a wide transparency range, from ultraviolet to mid-infrared wavelengths. They also have low characteristic phonon energies and can dissolve large concentrations of rare-earth ions. For these reason, they are extremely popular as hosts for rare-earth doped amplifiers and lasers operating in the UV-vis and mid-infrared regions.

Glass Transition Temperature is the approximate temperature at which a material changes from a supercooled liquid to an amorphous solid, or vice versa. The transition is marked by an abrupt but continuous change in slope of the specific volume and enthalpy versus temperature curves. Viscosity varies rapidly near the glass transition temperature, which is also sometimes called the softening temperature.

High Index Contrast refers to waveguides or devices fabricated using two or more materials that have very different refractive index. High index contrast is the basis for the confinement of light to very small cross-sectional area waveguides or very small volume optical cavities, either using total internal reflection or photonic bandgap effects. High index contrast thus is the basis for increased density of optical integrated circuits.

Integrated Optics/Photonics refers to the manufacture of photonic elements and circuits on a planar substrate, typically using thin film deposition, lithography, and etching steps. Typically, the substrate is a glass or semi-

conductor wafer and the photonic elements are guided wave devices.

Metastability is a term that refers to the non-equilibrium nature of glasses or amorphous solids. Amorphous solids have excess internal energy relative to the corresponding crystalline state or states of the same material. The method of manufacture, such as melt quenching, inhibits a transition to the lowest energy crystalline state.

Microphotonics refers to the chip-scale manufacture of optical and photonic waveguide circuitry, using processing techniques borrowed from the microelectronics industry. Related to this is the need for high-density integrated optics, as facilitated by high index contrast waveguides and photonic crystals. By usual definition, microphotonics refers specifically to the monolithic manufacture of optical and photonic elements on silicon (CMOS) chips.

Photoinduced Effects are changes in the properties of a glass induced by light, involving transitions between metastable states of the glass or changes in defect sites within the glass. Typically, a laser beam is used to locally modify the refractive index, density, absorption coefficient, etc. of the glass. These processes are widely used to pattern photonic structures such as Bragg gratings, waveguides, and refractive lenses into glasses.

Planar Lightwave Circuit or PLC refers to the industrially established processes for manufacturing integrated

optics devices in silica-based glasses deposited on silicon wafers. Typically, the glass layers are deposited by chemical vapor deposition or flame hydrolysis. These technologies were developed mainly for applications in fiber optics, and are widely used to manufacture wavelength multiplexers.

Reflow is the process of heating a glass above its glass transition temperature, to the point that its viscosity is sufficiently reduced to enable the material to flow. In combination with surface tension effects or other external forces, reflow is often exploited in the reshaping of optical devices.

Supercooling Temperature is the difference between the glass transition temperature and the in-use temperature for a glass-based device. For a large (small) supercooling temperature, the structural relaxation rate is low (high).

Structural Relaxation is essentially an aging effect associated with glasses. Because glasses are metastable materials with random network structures, they are inherently subject to short or long term changes in material properties. Often, structural relaxation is manifested by a change in specific volume (densification) at fixed temperature versus time. The rate of such changes is extremely sensitive to the difference between the glass transition temperature and the observation temperature. Structural relaxation can be induced rapidly by an annealing step, in which the glass is heated near its glass transition temperature for some period of time.

44. Optical Nonlinearity in Photonic Glasses

A brief review of optical nonlinearity in photonic glasses is given. For third-order nonlinearity, the relationship between two-photon absorption and nonlinear refractive index is considered using a formalism developed for crystalline semiconductors. Stimulated light scattering and supercontinuum generation in optical fibers are also introduced. Prominent resonant-type nonlinearity in particle-embedded glasses is described. For second-order nonlinearity, a variety of poling methods are summarized. Finally, it is pointed out that various photoinduced changes can appear when excited by linear and nonlinear optical processes, and this is related to glass structure.

References	1072

New developments in optical fibers and pulsed lasers have prompted increasing interest in optical nonlinearity in photonic glasses [44.1–3]. Third-order polarization yields several nonlinear phenomena, such as intensity-dependent absorption and intensity-dependent refractive index, which can be utilized in power stabilizers and all-optical switches. On the other hand, in high-power glass lasers, self-focusing effects arising from intensity-dependent increases in refractive index pose serious problems. Then again, the second-order polarization that occurs in poled glasses can be utilized in second harmonic generation for example. The present chapter provides a brief review of optical nonlinearity in *inorganic* glasses. At this point we should mention that, in many respects, organic polymers exhibit similar features to those of glass [44.4, 5]. In general, glass is more stable, while polymers can provide greater nonlinearity, so these two types of material are competitors in practical applications.

Glass also competes with crystals. A great advantage of glass is the ability to control its structure at three scales. First, the atomic composition of the glass can be tailored continuously. For instance, we can obtain nonlinear optical glass with any refractive index in the range of 1.4–3.2 at a wavelength of $\approx 1 \mu\text{m}$. Second, the atomic structure can be modified reasonably easily using, e.g., light beams. Such modifications may be regarded as photoinduced phenomena, which can be

employed in order to add second-order nonlinearity to selected regions and so forth. Lastly, macroscopic shapes can be changed into arbitrary bulk forms, fibers, thin layers and microparticles [44.6, 7].

Here, fiber and film waveguides may be very important for nonlinear applications for two reasons. One is that the light power density can be increased by reducing the lateral size, i. e. the film thickness or fiber diameter, to submicron scales. The other is, that fibers can provide long lengths for light–glass interactions that are not limited by diffraction. These scale factors produce apparent enhancements in nonlinear effects in glasses, although the intrinsic nonlinearity may be smaller than that in crystals.

Before proceeding further, it would be useful to introduce a nonlinear formula [44.4, 5]. For simplicity, we take the polarization P and the electric field E to be scalar quantities. Then, very simply, P can be written down in the cgs units as

$$P = \chi^{(1)}E + \chi^{(2)}EE + \chi^{(3)}EEE + \dots, \quad (44.1)$$

where the first term $\chi^{(1)}E$ depicts the conventional linear response, and $\chi^{(2)}$ and $\chi^{(3)}$ represent the second- and the third-order nonlinear susceptibilities. $\chi^{(1)}$ is related to the linear refractive index n_0 via $n_0 = \{1 + 4\pi\chi^{(1)}\}^{1/2}$. On the other hand, the second term provides such time dependence as $\sin\{(\omega \pm 2\omega)t\}$, so that it could produce dc and second-overtone (2ω) signals. In a similar way, the

Fig. 44.1a–d Schematic illustrations of (a) one-photon absorption, (b) two-photon absorption, (c) two-step absorption via a mid-gap state, and (d) a Raman-scattering process in a semiconductor with a valence band (VB) and a conduction band (CB)

third could modify the fundamental (ω) signal and generate a third-overtone (3ω). Nevertheless, since a refractive index changes with frequency, it is difficult in the overtone generations to satisfy the so-called phase-matching condition [44.4, 5], e.g. $\varphi_{3\omega} = 3\varphi_{\omega}$, where φ is the phase of electric fields in glasses. The, the fundamental-signal processing may be the most important. Microscopically, the nonlinear terms arise through several mechanisms, such as electronic, atomic (including molecular motions), electrostatic and thermal processes. Among these, electronic processes can provide the fastest responses, with fs–ps time scales, which will be needed for optical information technologies. Accordingly, we will focus on such processes from this point onwards.

The chapter is divided up as follows. In Sect. 44.1, we treat conventional glasses. These are optically isotropic, which gives $\chi^{(2)} = 0$, because the isotropic structure appears to be centrosymmetric. In this case, the lowest nonlinear term becomes $\chi^{(3)}EEE$. When $\chi^{(3)}EEE$ can be written as $\chi^{(3)}IE$, where I is the light intensity, we can define the refractive index n as $n = n_0 + n_2I$, where n_2 is sometimes called the second-order index of refraction [44.5]. In nonlinear optics, this notation poses problems due to the definitions of several parameters. Therefore, the con-

version $n_2(\text{cm}^2/\text{W}) \approx 0.04\chi^{(3)}(\text{esu})/n_0^2$ is frequently employed [44.5]. On the other hand, for light absorption, which is proportional to $\langle E dP/dt \rangle$, where $\langle \dots \rangle$ represents a time average, we need to take the imaginary parts of $\chi^{(1)}$ and $\chi^{(3)}$, which cause one- and two-photon absorption, into account (Fig. 44.1). In such cases, an effective absorption coefficient can be written as $\alpha(\text{cm}^{-1}) + \beta(\text{cm}/\text{W})I(\text{W}/\text{cm}^2)$; n_2 and β will be connected through nonlinear Kramers–Kronig relations.

Section 44.2 focuses upon noncentrosymmetry. From the mid-1980s onwards, several kinds of poling treatments have been found to add $\chi^{(2)}$ to glasses [44.8]. For instance, Österberg and Margulis [44.9] demonstrated intense second harmonic generation in laser-irradiated glass fibers. Such work began with silica, and has more recently been directed towards more complicated glasses. The magnitude of $\chi^{(2)}$ seen in this case may be smaller than those observed in crystals, due to the disordered atomic structures in glasses, but the structural controllability may offer some advantages.

Section 44.3 introduces glasses incorporating fine semiconductor and metal particles. Such nanostructured glasses are known to exhibit large optical nonlinearities [44.4, 5, 10]. However, as will be described, their wider features remain to be studied.

In Sect. 44.4 we consider photoinduced phenomena. The intense light needed to produce optical nonlinearity is likely to modify the structure of glass. Light that is even more intense may cause damage. While this damage can be useful for optical engraving, the structural modification may ultimately be more important. Actually, fiber Bragg gratings [44.1, 11] have been produced commercially using excimer lasers, and nonlinear optical excitation may play an important role in these. Three-dimensional modifications are also produced through controlled light focusing [44.12]. Section 44.5 provides a summary of the chapter. This chapter is based on author's recent review [44.13].

44.1 Third-Order Nonlinearity in Homogeneous Glass

44.1.1 Experimental

Substantial data are available for n_2 at transparent wavelengths [44.4]. However, to the author's knowledge, all such experiments have utilized lasers, and no spectral dependence has been reported. We should also note that, in comparison with n_0 measurements, n_2 evaluations are much more difficult [44.4]. The biggest

difficulty, which is common to all nonlinear experiments, is the light intensity. Normally, light is pulsed and focused, producing complex temporal and spatial profiles, which in turn means that intensity evaluations are not straightforward. For instance, if the profile is Gaussian, can we simply use the peak value to evaluate the nonlinearity? Because of such measuring difficulties and also some other specific problems inherent to

Table 44.1 Linear (E_g , n_0 , α_0) and nonlinear (n_2 , β , β_{\max}) optical properties and figures of merit ($2\beta\lambda_0/n_2$, n_2/α_0) in some glasses. E_g is the optical bandgap energy [44.12], n_0 is the refractive index [44.12], α_0 is the attenuation coefficient [44.16], n_2 is the intensity-dependent refractive index [44.4, 5, 12], β is the two-photon absorption coefficient [44.16], and β_{\max} is the maximum value. Except for E_g and β_{\max} , the values are evaluated at a wavelength of 1–1.5 μm . BK-7 is a borosilicate glass and SF-59 indicates data for lead-silicate glasses with $\approx 57\text{mol.}\%$ PbO

Glass	E_g (eV)	n_0	α_0 (cm^{-1})	n_2 (10^{-20} m^2/W)	β (cm/GW)	β_{\max} (cm/GW)	$2\beta\lambda_0/n_2$	n_2/α_0 (cm^3/GW)
SiO ₂	10	1.5	10^{-6}	2	$< 10^{-2}$	1	< 10	0.2
BK-7	4	1.5		3				
SF-59	3.8	2.0		30	$< 10^{-1}$	10		
As ₂ S ₃	2.4	2.5	10^{-3}	200	10^{-2}	50	0.1	0.02
BeF ₂	10	1.3		0.8				

glasses, reported n_2 values vary, even for a reference SiO₂ glass, over the range $1\text{--}3 \times 10^{-20} \text{ m}^2/\text{W}$ [44.4]. In other glasses, values that differ by a factor of ≈ 10 have been reported [44.4, 14, 15].

However, we can see a general trend in n_2 in Table 44.1. Halide glasses (BeF₂) have the smallest values, light metal oxides (BK-7) and SiO₂ have similar values, heavy metal oxides such as PbO-SiO₂ (SF-59) have larger values, while the largest belong to the chalcogenides (As₂S₃) [44.4, 10]. The largest value reported so far may be $n_2 = 8 \times 10^{-16} \text{ m}^2/\text{W}$, seen in Ag₂₀As₃₂Se₄₈ at wavelength of 1.05 μm [44.21], which is $\approx 10^4$ times as large as that of SiO₂.

Figure 44.2 shows β spectra for SiO₂, As₂S₃ and two PbO-SiO₂ glasses [44.16]. Bi₂O₃-B₂O₃ glasses (Imanishi et al., [44.22]) exhibit similar features to those of lead glass. We can see that all of the β spectra seem to have maxima at midgap regions, $\hbar\omega \approx E_g/2$. However, this is not an absolute rule, since at $\hbar\omega \geq 2.0 \text{ eV}$ As₂S₃ provides two-step absorption (Fig. 44.1), which masks the two-photon absorption signal [44.20]. We also see that the maximal β ($\approx 10^0 \text{ cm}/\text{GW}$) in SiO₂ is markedly smaller than those belonging to the other glasses. Note that such a marked difference does not exist in maximal α , which is $\approx 10^6 \text{ cm}^{-1}$ at the super-bandgap regions of SiO₂ and As₂S₃. It may be worth mentioning here that two-photon excitation produces photocurrents in some glasses [44.23, 24].

Fig. 44.2 One- (dashed line) and two-photon (solid line) absorption spectra, α and β , in SiO₂ [44.17, 18], 38PbO – 62SiO₂, 68PbO – 32SiO₂ [44.19], and As₂S₃ [44.20]. For SiO₂, in transparent regions ($\hbar\omega \leq 8.0 \text{ eV}$) α should be regarded as an attenuation coefficient; these are not reproducible, probably due to impurities, defects and light scattering. The dotted line for As₂S₃ at $\hbar\omega \geq 2.0 \text{ eV}$ indicates two-step absorption

44.1.2 Theoretical Treatment

For $\chi^{(3)}$, theoretical treatments of glasses, liquids, and crystals are largely the same. Glasses and liquids can be treated similarly in the sense that both are optically isotropic. Hence, many ideas stemming from types of chemical bond pictures have been proposed [44.5]. On the other hand, the magnitude of $\chi^{(3)}$ in glass appears to be similar to that in the corresponding crystal, since their electronic structures are both governed by short-range atomic structures, within $\approx 0.5 \text{ nm}$ [44.25], which is much shorter than the wavelength ($\approx 500 \text{ nm}$) of visible light. Specifically, since n_2 is governed by integrated electronic absorption (44.8), the magnitudes are roughly the same in glass and crystal. For instance, in crystalline and glassy SiO₂ at near-infrared wavelengths, the difference in the n_2 values of both seems to be comparable with their experimental accuracy; i. e. the values for crystalline and glassy SiO₂ are $\approx 1.14 \times 10^{-13}$ and $0.85 \times 10^{-13} \text{ esu}$ respectively [44.4]. Then, using a formula derived for semiconductor crystals, we can apply

Fig. 44.3 The Sheik–Bahae relation $n_2n_0 = KG(\hbar\omega/E_g)/E_g^4$ (solid line), related data (solid symbols), the Moss rule $n_0^4E_g = 77$ (dashed line), and related data (open symbols) for an oxide (circles), sulfide (triangles) and selenide (squares). The four data for As_2Se_3 are obtained from different publications, while those for PbO-SiO_2 with slightly different E_g correspond to different compositions. The illustration is modified from its previous form [44.16] due to the additions of $\text{Ag}_{20}\text{As}_{32}\text{Se}_{48}$ [44.21], Bi_2O_3 -silica glasses [44.26], $35\text{La}_2\text{S}_3 - 65\text{Ga}_2\text{S}_3$ [44.27], and $15\text{Na}_2\text{O} - 85\text{GeO}_2$ [44.28]

a kind of band picture to glasses [44.16], as described below.

Estimation of Nonlinear Refractivity

Several semi-empirical relationships have been proposed for $\chi^{(3)}$ or n_2 [44.5]. Such relations are useful, since nonlinear optical constants are much more difficult to measure than linear constants. Naturally, since they are simplifications they are also less accurate. The simplest may be the one provided by Wang, $\chi^{(3)} \approx \{\chi^{(1)}\}^4$, which can be regarded as a generalized Miller's rule [44.5]. Boling et al. [44.29] have also derived some relations, among which the simplest may be

$$n_2(10^{-13} \text{ esu}) \approx 391(n_d - 1)/v_d^{5/4}, \quad (44.2)$$

where n_d is the refractive index at the d-line ($\lambda = 588 \text{ nm}$) and v_d is the Abbe number. This relation contains only two macroscopic parameters, which can be

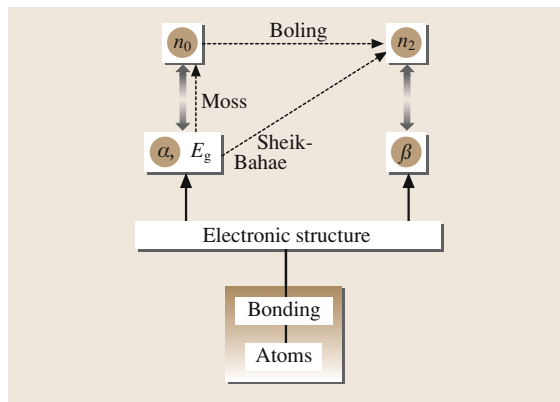

Fig. 44.4 Relationship between atomic structure, electronic structure, linear absorption α including bandgap energy E_g , linear refractive index n_0 , two-photon absorption β , and nonlinear refractive index n_2 . Absorption and refraction are related by the linear and nonlinear Kramers–Kronig relations (double arrows). The Moss rule may be regarded as a simplified Kramers–Kronig relation. The Boling and Sheik–Bahae relations connect n_0 and E_g to n_2 , respectively

easily evaluated, and so it has often been used to estimate n_2 . It actually provides a good approximation for small n_d glasses with $n_d \leq 1.7$ [44.29]. For high n_d glasses, Lines [44.14] proposes a relation that also contains the atomic distance, and others derive more complicated formula [44.30, 31]. Ab initio calculations for TeO_2 -based glasses have also been reported recently [44.32]. However, these relations cannot predict wavelength dependence (Fig. 44.5). The estimated n_2 may be regarded as a long-wavelength limit. In addition, the material is regarded as transparent, so relations between n_2 and β cannot be found.

Nonlinear optical properties of semiconductor crystals have been studied fairly deeply [44.5], and applying the same concepts to glasses appears to be tempting. Tanaka [44.16] has adopted a band picture, which was developed by Sheik-Bahae et al. [44.33], to some glasses. Their concept gives a universal relationship of

$$n_2 = KG(\hbar\omega/E_g)/(n_0E_g^4), \quad (44.3)$$

for crystals with energy gaps of 1–10 eV, where K is a fixed constant and $G(\hbar\omega/E_g)$ is a spectral function (E_g is the bandgap energy). For E_g in glasses, we can take the so-called Tauc gap [44.25] if it is known, or otherwise the photon energy $\hbar\omega$ at $\alpha \approx 10^3 \text{ cm}^{-1}$. As shown in Fig. 44.3, the universal line gives reasonable agreement with published data, while the agreement is

Fig. 44.5 Spectral dependence of linear absorption α , linear refractive index n_0 , two-photon absorption β , and intensity-dependent refractive index n_2 in an ideal amorphous semiconductor with energy gap E_g . Vertical scales are arbitrary

not satisfactory as it is for crystals [44.33]. The poorer agreement for glasses may be partly due to experimental difficulties. In addition, band tail states probably cause larger deviations in smaller bandgap glasses such as $\text{Ag}_{20}\text{As}_{32}\text{Se}_{48}$. Incidentally, as shown by the dashed line in the figure, the Moss rule $n_0^4 E_g = 77$ [44.34], which was originally pointed out for crystalline semiconductors, also gives satisfactory fits for glasses.

Nonlinear Kramers–Kronig Relationship

We can take another approach in order to obtain unified insight into optical nonlinearity (n_2 and β). In this case, we start with absorption and then obtain the refractive index using Kramers–Kronig relationships. As illustrated in Fig. 44.4, this approach is able to provide a complete understanding of atomic structure and optical properties, since absorption spectra can be related to electronic structure more directly.

It is well-known that, for glasses, and neglecting momentum conservation rules, $\alpha(\hbar\omega)$ and $\beta(\hbar\omega)$ can be written as [44.16]

$$\alpha(\hbar\omega) \propto |\langle \phi_f | H | \phi_i \rangle|^2 \int D_f(E + \hbar\omega) D_i(E) dE, \quad (44.4)$$

$$\begin{aligned} \beta(\hbar\omega) &\propto |\Sigma_n \langle \phi_f | H | \phi_n \rangle \langle \phi_n | H | \phi_i \rangle / (E_{ni} - \hbar\omega)|^2 \\ &\times \int D_f(E + 2\hbar\omega) D_i(E) dE, \end{aligned} \quad (44.5)$$

where H is the perturbation Hamiltonian, ϕ is a related electron wavefunction, and D is the density of states, and the subscripts i , n , and f represent the initial, intermediate, and final states. α and β are linked to the electronic structure, i. e. the wavefunctions and densities of states, which is determined by the atomic species and bonding structures involved [44.25]. In this case, $n_0(\omega)$ is expressed using the conventional Kramers–Kronig relation as [44.5]

$$n_0(\omega) = 1 + (c/\pi) \wp \int [\alpha(\Omega)/(\Omega^2 - \omega^2)] d\Omega. \quad (44.6)$$

For a nonlinear response Δn , Hutchings et al. [44.35] have derived the relation

$$\Delta n(\omega; \zeta) = (c/\pi) \wp \int [\Delta\alpha(\Omega; \zeta)/(\Omega^2 - \omega^2)] d\Omega, \quad (44.7)$$

where $\Delta\alpha$ is the nonlinear absorption induced by an excitation at ζ and probed at Ω . Note that this relation is derived from the causality principle for nondegenerate cases, e.g., two-beam experiments with different photon energies, Ω and ζ . However, this relation may also be applied to degenerate cases ($\Omega = \zeta$) as a rough approximation as [44.36]

$$n_2(\omega) = (c/\pi) \wp \int [\beta(\Omega)/(\Omega^2 - \omega^2)] d\Omega. \quad (44.8)$$

Using these formulae, we can roughly predict how β and n_2 depend upon E_g . Equation (44.5) suggests that $\beta \propto 1/E_g^2$, provided that the E_g dependence is governed by $|\Sigma_n 1/(E_{ni} - \hbar\omega)|^2$. This relation may be consistent with the material dependence shown in Fig. 44.2. That is, $\beta_{\max} \propto 1/E_g^2 \approx 1/E_g^3$. Note that this E_g dependence is comparable to $\beta \propto 1/E_g^3$, which is theoretically derived and experimentally confirmed for crystalline semiconductors [44.5, 33]. Then, putting $\beta \propto 1/E_g^2$ into (44.8), and assuming $\int [1/(\Omega^2 - \omega^2)] d\Omega \propto 1/E_g^2$, we obtain $n_2 \propto 1/E_g^4$, which is consistent with (44.3).

Under some plausible assumptions, we can also calculate the spectral dependence of β and n_2 for an ideal amorphous semiconductor, which contains no gap states [44.37]. Figure 44.5 shows that, at $\hbar\omega = E_g/2$, $\beta = 0$ and n_2 is maximal. This is similar to some degree to the feature at $\hbar\omega = E_g$ for α and n_0 . The figure also shows that β becomes maximal at $E_g/2 - E_g$. Note, however, that it is not clear whether we can link this photon energy dependence to the experimental results shown in Fig. 44.2, since the observed spectra appear to have fairly sharp peaks.

Figure of Merit

Several figures of merit have been proposed for evaluating optical devices which utilize n_2 . For instance, Mizrahi et al. [44.40] and others [44.15, 21, 41] emphasize the negative effects of two-photon absorption, and provide the criterion that $2\beta\lambda_0/n_2 < 1$. Then, using the above E_g dependence, we see that $\beta/n_2 \approx E_g^2$, so that small E_g materials are preferable. Actually (as also listed in Table 44.1), in this figure, As_2S_3 appears to be better than SiO_2 . However, the criterion implicitly neglects α . Lines [44.14] uses n_2/α instead. Here, α arises from the so-called residual absorption, which is difficult to estimate quantitatively. In addition, it is the attenuation α_0 instead of the absorption α that could be decisive. Table 44.1 shows that, in this measure, SiO_2 behaves better than As_2S_3 . These figures of merit, however, have presumed only nonresonant electronic contributions with sub-ps responses. More recently, Jha et al. [44.10] utilize $n_2/\tau\alpha$, where τ is the relaxation time. Nevertheless, theoretical predictions of τ remain to be studied.

The most appropriate definition of the figure of merit naturally depends upon the application of interest. For instance, for an optical fiber device, the maximum length might be ≈ 1 m [44.42], since the device must be compact and fast. In this case, the light absorption, which arises from $\alpha + \beta I$, should be suppressed to below 10^{-2} cm^{-1} , or the light propagation loss must be smaller than $\approx 1 \text{ dB/m}$. However, for optical integrated circuits, an effective propagation distance may be $\approx 1 \text{ cm}$, in which the attenuation could be as large as 10^0 cm^{-1} .

We can suggest another idea by taking the spectral dependence shown in Fig. 44.5 into account. That is, the best material that has n_2 at some $\hbar\omega$ is the one which satisfies a bandgap condition of $\hbar\omega = E_g/2$, where α and β are zero and n_2 becomes maximal, provided that there is no gap-state absorption. In practical glass samples, absorption due to impurities, dangling bonds such as E' centers in oxide glasses [44.11, 25], and wrong bonds in chalcogenide glasses [44.25, 37] cannot be neglected. Actually, we can see in Table 44.1 and Fig. 44.2 that residual attenuation exists in nominally transparent regions, parts of which are undoubtedly caused by absorption [44.43]. Note that these mid-gap states also give rise to two-step absorption (Fig. 44.1). We also cannot neglect photoinduced phenomena induced by these photoelectronic excitations (Sect. 44.4). Selecting an appropriate glass for a specific application is, therefore, not a straightforward process.

Fig. 44.6 Output spectra from a Raman fiber amplifier [44.38] and from a supercontinuum fiber generator [44.39] excited by 1483 nm light (schematic illustration)

44.1.3 Stimulated Light Scattering and Supercontinuum Generation

Recently, stimulated Raman scattering has attracted considerable interest, since it can be utilized for broadband light amplification [44.1, 5]. As illustrated in Fig. 44.1d, stimulated Raman scattering can be regarded as a kind of nondegenerate two-photon process. However, in contrast to two-photon absorption, one photon is absorbed by a virtual state at the same time as another photon is emitted in Raman scattering. As with conventional stimulated light emission, when the incident light is intense, the Stokes-shifted light can be amplified. The nonlinear polarization related to this is given by $P^{(3)}(\omega_s) \propto i\chi_R^{(3)} I(\omega_L) E(\omega_s)$, or the emitted light intensity is $\Delta I(\omega_s) \propto \chi_R^{(3)} I(\omega_L) I(\omega_s)$, where ω_L and $\omega_s (< \omega_L)$ are the exciting laser frequency and the Stokes-shifted frequency.

Most experiments have been performed using optical fibers [44.1, 42] in order to obtain long interaction lengths. For instance, as illustrated in Fig. 44.6, Raman fiber amplifiers comprising 5–10 km lengths of silica can provide broadband gains of $\approx 10 \text{ dB}$ [44.38]. Raman lasers using silica microspheres of diameter $\approx 70 \mu\text{m}$ [44.7] are also interesting examples. On the other hand, stimulated Brillouin scattering in glasses has also been explored [44.1, 4].

Supercontinuum generation in silica fibers has now been studied intensively [44.4, 39, 44]. When pulsed or CW light propagates through a nonlinear medium, it may undergo spectral broadening [44.5].

For instance, as illustrated in Fig. 44.6, a 350 m single-mode fiber excited by a 2.22 W CW laser with a wavelength of 1.483 μm can emit 2.1 W over a broad spectrum of 1.43–1.53 μm [44.39]. Note that, unlike the stimulated light scattering described above, light of a shorter wavelength is also generated in this process. Such a spectral-

conversion fiber could be utilized as a broadband optical amplifier. The phenomenon appears under strong and prolonged nonlinear interactions, and accordingly, several mechanisms such as intensity-dependent refractive index changes, third harmonic generation and stimulated Raman scattering could be responsible [44.39].

44.2 Second-Order Nonlinearity in Poled Glass

It has been discovered that several kinds of poling methods can add second-order nonlinearity to glasses [44.8]. At least five kinds have been demonstrated, which are listed in Table 44.2. Note that similar procedures are also employed for polymers. Most experiments utilize second harmonic signals to evaluate $\chi^{(2)}$ and, less commonly, electro-optical effects. Practical applications remain to be studied, while, for second-harmonic generations, the optical phase matching between exciting and nonlinearly-generated light is a prerequisite [44.45].

This so-called optical poling was demonstrated by *Österberg and Margulis* [44.9] using optical fibers. They found that exposing Ge-doped optical fibers of length ≈ 1 m to 70 kW Nd:YAG laser light for ≈ 1 h could increase the second-harmonic signal to 0.55 kW. *Stolen and Tom* [44.46] utilized two light beams (x1 and x2, of Nd:YAG laser light) for induction, which reduced the exposure time to ≈ 5 min. However, the method was only practical for optical fibers, since the nonlinearity induced was relatively small, $\chi^{(2)} \approx 10^{-4}$ pm/V. Second, so-called thermal poling, which was actually electrothermal in nature, was demonstrated in *bulk* SiO₂ samples by *Myers et al.* [44.47]. The nonlinearity induced, ≈ 1 pm/V, which was evaluated from the second harmonic signals of 1.06 μm laser light, is of a similar magnitude to that in quartz. Since this nonlinearity is reasonably large, this method has been widely applied to other glasses, such as PbO-SiO₂ [44.48], Nb₂O₅-B₂O₃-P₂O₅-CaO [44.49], and TeO₂-Bi₂O₃-ZnO [44.50]. Third, *Okada et al.* [44.51] demonstrated the corona-discharge poling at $\approx 200^\circ\text{C}$ of 7059 films deposited onto Pyrex glass substrates. This corona-poling procedure has often been employed for organic polymers. Fourth, electron-beam poling of PbO-silica glass was shown to produce ≈ 1 pm/V [44.52]. An advantage of this method is its high resolution, which may hold promise in the fabrication of optical integrated circuits, despite the fact that a vacuum is needed. *Liu et al.* (2001) [44.53] applied the method to chalcogenide glasses, which produced ≈ 1 pm/V. Proton implantation into silica can also add

Table 44.2 Reported poling methods, applied objects, typical procedures, and induced $\chi^{(2)}$ values in silica. For references, see the main text. The $\chi^{(2)}$ values listed are compared with $\chi_{11}^{(2)} = 1$ pm/V in crystalline SiO₂ and $\chi_{22}^{(2)} = 5$ pm/V in LiNbO₃

Method	Object	Procedure	$\chi^{(2)}$ (pm/V)
Optical	Fiber	Nd:YAG laser, 1 h	10^{-4}
Thermal	Bulk	4 kV, 300 $^\circ\text{C}$, 1 h	1
Corona	Film	5 kV, 300 $^\circ\text{C}$, 15 min	1
e-beam	Bulk	40 kV, 10 mA, 10 min	1
Proton	Bulk	500 kV, 1 mC, 100 s	1
UV	Bulk	ArF laser, 10 kV	3

a $\chi^{(2)}$ of ≈ 1 pm/V [44.54]. Sixth, *Fujiwara et al.* (1997) demonstrated UV poling in Ge-doped SiO₂ subjected to electric fields of $\approx 10^5$ V/cm. The $\chi^{(2)}$ induced is reported to be ≈ 3 pm/V, comparable to that in LiNbO₃.

Two poling mechanisms of note have been proposed [44.8]. One is that space charge produces a built-in electric field of $E_{\text{DC}} (\approx 10^6 \text{ V/cm})$, which induces an effective $\chi^{(2)}$ of $3E_{\text{DC}}\chi^{(3)}$ [44.46]. Here, E_{DC} is governed by the migration of ions such as Na⁺ under applied or generated electric fields [44.55]. In agreement with this idea, $\chi^{(2)}$ decays with a time constant of 10^1 – 10^6 days at room temperature, which is connected to the alkali ion mobility [44.55]. The other idea is that oriented defects such as E' centers are responsible. It is reasonable to assume that UV excitation produces defective dipoles, which are oriented with the static electric field.

It may be reasonable to assume that the dominant mechanism depends upon the poling method. Actually, we can divide the procedures listed in Table 44.2 into two types, depending upon whether or not the glass is heated during the poling process. The heating tends to enhance macroscopic ion migration,

while it can also relax microscopic defect orientations at the same time [44.25]. Therefore, it seems that the ion migration is responsible in thermal and coronal poling, while defect orientation dominates in the other methods. In this context, poling at low temperatures may be a promising way of enhancing defect orientation.

44.3 Particle-Embedded Systems

Glasses that contain nanoparticles of metals [44.65, 66] and semiconductors [44.67] have attracted considerable interest due to their unique third-order nonlinearities. Table 44.3 lists several recent results. Such glasses containing dispersed nanoparticles can be prepared by a variety of physical and chemical methods, e.g., vacuum deposition and sol-gel techniques [44.4, 65, 68]. For semiconductor systems, a lot of work has also been investigated in semiconductor-doped color glass filters [44.67], which are now commercially available.

These nanoparticle systems work efficiently at close to the resonant wavelengths of some electronic excitations. This feature produces at least three characteristics. First, the imaginary, not the real, part of $\chi^{(3)}$ may be more prominent. Accordingly, Table 44.3 compares absolute values. Second, the system exhibits a strong spectral dependence [44.4, 69]. For instance, Au-silica and CdSSe-silica are efficient at ≈ 580 nm and ≈ 800 nm [44.4]. Third, the response time τ and the linear absorption α tend to become longer and higher. Actually, a trade-off between $\chi^{(3)}$ and τ and α seems to exist. For instance, CdSSe-dispersed glasses show $\chi^{(3)}$ value of $\approx 10^{-9}$ esu with τ value of ≈ 20 ps, while Au-dispersed glasses give $\approx 10^{-11}$ esu and ≈ 1 ps, respectively [44.4]. Linear absorption can be as large as 10^4 cm $^{-1}$ [44.65], so these systems can be utilized as

In so-called *glass ceramics*, embedded crystals seem to be responsible for prominent $\chi^{(2)}$ [44.50, 56, 57]. For instance, *Takahashi* et al. [44.57] demonstrated that oriented Ba $_2$ TiSi $_2$ O $_8$ crystals are produced in BaO-TiO $_2$ -SiO $_2$ glass by heat treatment at 760 °C for 1 h, which gives a prominent $\chi^{(2)}$ of ≈ 10 pm/V. $\chi^{(2)}$ can also be generated at interfaces [44.58].

small devices, not as fibers. Note that, in pure silica at nonresonant infrared wavelengths, $\chi^{(3)} \approx 10^{-13}$ esu, $\tau \approx 10$ fs, and $\alpha \leq 10^{-5}$ cm $^{-1}$ [44.65]. As is suggested above, the particle-embedded system should surmount two problems for wide applications. One is the reduction of linear attenuation, including absorption and scattering, and the other is the shift of resonant wavelengths to the optical communication region, 1.3–1.5 μ m. Is such a shift possible? What are the mechanisms that give rise to these prominent nonlinearities in particle-embedded systems?

When the particle is a semiconductor such as CuCl and CdSSe, excitons or confined electron-hole pairs are responsible [44.67]. Specifically, the excitons in semiconductor particles behave as two-level systems, and at the resonance frequency, $|\chi^{(3)}|$ is written as

$$|\chi^{(3)}| \approx \text{Im}\chi^{(3)} \propto |\mu|^4 N T_1 T_2^2, \tag{44.9}$$

where μ is the dipole moment of the exciton, N is the particle number, T_1 (≈ 100 ps) is the lifetime of the exciton, and T_2 (\approx fs) is the dephasing time. A quantitative estimation predicts that closely packed CuCl particles of radius 40 nm could provide a $|\chi^{(3)}|$ enhancement of a factor of $\approx 10^3$ when compared with the bulk value [44.70].

When metal particles such as spherical Au particles with diameters of 10–50 nm are used, we can envisage

Table 44.3 Several recently reported particle systems, along with their preparation methods, $|\chi^{(3)}|$ values, and response times τ at the measured wavelength λ , as well as references. PLD and VE depict pulsed laser deposition and vacuum evaporation

System	Preparation	$ \chi^{(3)} $ (esu)	τ	λ (nm)	Reference
Au (15 nm)/ silica	Shell structure	10^{-9}	2 ps	550	[44.59]
Cu (2 nm)/Al $_2$ O $_3$	PLD	10^{-7}	5–450 ps	600	[44.60]
Ag (20 nm)/BaO	VE	10^{-10}	0.2 ps	820	[44.61]
Fe (4 nm)/BaTiO $_3$	PLD	10^{-6}		532	[44.62]
SnO $_2$ (10 nm)/silica	Sol-gel	10^{-12}		1064	[44.63]
CdS (4 nm)/silica	Sol-gel	10^{-11}		500	[44.64]

local field enhancement and dynamic responses from conduction electrons, including plasmon effects [44.65, 66, 71]. The result is approximately written as

$$\chi^{(3)} \approx p_m \chi_m^{(3)} |3\varepsilon_h/(\varepsilon_m + 2\varepsilon_h)|^2 \{3\varepsilon_h/(\varepsilon_m + 2\varepsilon_h)\}^2, \quad (44.10)$$

where p_m is the volume fraction of the metal particles, $\chi_m^{(3)}$ is the bulk nonlinearity of the metal, and ε_h and ε_m are the linear dielectric constants of the host (glass) and the metal. The nonlinearity of the host is neglected here for the sake of simplicity. Note that ε_h can be real, while ε_m is complex. We see that the metal's nonlinearity $\chi_m^{(3)}$ is decreased by the volume factor p_m , while $\chi_m^{(3)}$ may be enhanced by local fields if $\text{Re}(\varepsilon_m + 2\varepsilon_h) \approx 0$, which determines the resonance wavelength. In agreement with this model, an Au-dispersed glass, for instance, gives a greater $\chi^{(3)}$ than that of an Au film [44.5].

However, since these systems are complex, consisting of particles and a glass matrix, a variety of situations arise. For the particle, as well as particle species, we need to consider size, size distribution, shape and concentration. Here, needless to say, a narrow size

distribution is preferred for investigating fundamental mechanisms. The shape may be spherical, ellipsoidal, rod, and so forth. The concentration determines the mean separation distance between particles. As the concentration increases, electrical particle–particle interactions appear [44.59], and then the particles eventually percolate [44.60], which may produce dramatic changes in the nonlinear response. The matrix seems to be of secondary importance. Actually, liquids and organic materials have been employed as well as glasses [44.4]. However, some reports suggest that the nonlinearity is greatly affected by the surface states of the semiconductor particles [44.72] and by the dielectric constant of the matrix surrounding the metallic particles [44.4].

Lastly, it may be worth mentioning two recent results. One is that particles can be arrayed to produce photonic structures that exhibit novel nonlinear properties, such as light confinement [44.73]. The other is the generation of second harmonic signals from oriented ellipsoidal Ag nanoparticles [44.74]. Oriented particle structures have been produced in silica through tensile deformation and simultaneous heating, and this may be regarded as a kind of mechanical poling.

44.4 Photoinduced Phenomena

The intense pulsed light employed to produce nonlinear effects is also likely to produce a variety of transitory and (quasi-)stable optical changes [44.72, 75]. Photochromic effects induced by sub-gap light are the result of transitory electronic changes [44.76]. The increase in the refractive index of SiO₂ induced by fs–ns laser light

Fig. 44.7 Different relaxation paths from bandgap excitation due to one-photon (*left*) and two-photon (*right*) processes. For instance, the one-photon and two-photon excitations induce bonding strains and defect alterations

with $\hbar\omega \approx 1 \approx 5$ eV is known to occur along with quasi-stable structural changes [44.11, 77]. The optical poling described in Sect. 44.2 can be regarded as a kind of photoinduced anisotropy. When the light is more intense than 1 GW/cm^2 – 1 TW/cm^2 , depending on the duration of the light pulse, permanent damage is likely to occur [44.5]. These photosensitive changes are induced by electronic excitations, which may be triggered by one-photon and multiphoton processes, depending upon the photon energy and the light intensity.

Are these photoinduced phenomena really excited by nonlinear processes? For instance, when a photoinduced phenomenon is induced by exposure to light of photonic energy $\hbar\omega \approx E_g/m$, where m is an integer, it is often asserted that m -photon absorption is responsible. Nevertheless, the phenomenon may be triggered by one-photon absorption by mid-gap states, which give weak absorption tails (Fig. 44.2) arising from defective structures in the glass [44.25, 78]. Otherwise, it may be triggered by m -step absorption processes [44.79], consisting of m one-photon absorptions in succession (Fig. 44.1c). These processes have probably been overlooked when analyzing experimental results.

In addition, as schematically illustrated in Fig. 44.7, the structural changes induced by linear and nonlinear excitation are not necessarily the same. Tanaka has demonstrated using As_2S_3 that the bandgap excitations produced by one-photon and two-photon absorption produce different changes [44.78]. One-photon excitation leads to photodarkening, while two-photon excitation results in an increase in the refractive index with no photodarkening. In these phenomena, temperature rises upon intense exposure can be neglected. Such changes related to excitation processes can appear in glasses because the *localized* atomic wavefunction plays an important role, in contrast to the extended Bloch

wavefunctions in crystals. For instance, as we can see from (44.4), one-photon excitation occurs between wavefunctions with different parities, such as from s to p orbitals, since H is an odd function. In contrast, (44.5) shows that two-photon excitation can occur between states of the same parity states, such as from p to p. In addition, the $1/(E_{ni} - \hbar\omega)$ in the equation leads to the possibility of *resonant and localized* two-photon excitation if $E_{ni} - \hbar\omega \approx 0$ is satisfied for a mid-gap state. In such cases, the mid-gap state selectively absorbs the excitation energy, leading to an atomic change which shows itself as a macroscopic photoinduced phenomenon.

44.5 Summary

At present, there is a big gap between the science and the technology of glasses. From a physical point of view, glass science lags far behind crystal science, mainly due to experimental difficulties associated with atomic structure determination and the theoretical unavailability of Bloch-type wavefunctions. On the other hand, it is now difficult to imagine a world without optical fibers. These contrasting situations are promoting a deeper understanding of nonlinear photonic glasses and are leading to an increasingly wide range of applications for such glasses.

Third-order optical nonlinearity in homogeneous glasses has been studied in a fair amount of detail. Substantial experimental data have been obtained for n_2 , which have been analyzed using empirical relations such as those from Boling. In contrast, less work has been done on the nonlinear absorption β . In the present article, therefore, we have tried to present, in a coherent way, the absorption and the refractive index using semiconductor terminology. This approach can be used to connect nonlinear properties to the energy gap. However, little work has been done on the dynamics associated with this field. For instance, it is difficult to theoretically predict the response time τ in a glass at a particular excitation energy.

Two inhomogeneous systems have aroused increasing interest. One is poled or crystallized glass. Enhanced second-order nonlinearity has been reported for such systems, and this can sometimes be added selectively to a region. The other is the particle-embedded system, which can give greater third-order nonlinearity, and in some cases enhanced second-order nonlinearity too. However, the mechanism associated with this system remains to be studied. One experimental problem is to find a method that can reproduce particles of a fixed size and shape in arbitrary concentrations. These two inhomogeneous systems can be combined using photonic structure concepts, which will be of interest for future applications.

Finally, nonlinear optical excitations appear to play important roles in a variety of photoinduced phenomena in glasses. However, fundamental studies are still lacking in this area. The phenomenon of interest may be nonlinear in nature, or the linear excitation of gap states may trigger successive changes. Attempting to understand the nonlinear photo-electro-structural process will provide a challenging problem.

45. Nonlinear Optoelectronic Materials

In a nonlinear optical material, intense light alters the real and imaginary components of the refractive index. The nonlinear response of the real part of refractive index modifies the phase of propagating light, while the imaginary part describes the change in absorption. These illumination-dependent properties of nonlinear materials provide the basis for all-optical switching—the ability to manipulate optical signals without the need for optical–electronic–optical conversion.

In this chapter we review the physical processes underlying the illumination-dependent refractive index. We review the real and imaginary nonlinear response of representative groups of materials: crystalline semiconductors, organic materials, and nanostructures, and we examine the practical applicability of these groups of materials to all-optical optical switching. We identify the spectral regions which offer the most favorable nonlinear response as characterized using engineering figures of merit.

45.1 Background

Optical fiber provides a suitable medium in which it is possible to reach tremendous transmission rates over long distances [45.1]. The maximum information-carrying capacity has been estimated to be around 100 Tbps [45.2]. Very high data rates can be achieved using a combination of wavelength- and time-division multiplexing techniques (WDM and TDM). WDM involves sending many signals in parallel at closely spaced wavelengths along the same fiber, while TDM allows close spacing in time of bits in a single channel.

While there exist means to produce, transfer, and detect information at a very high bandwidth, there is a need for more agility in photonic networks.

The agility of present-day optical networks is limited by the electronic nature of a very important function: the processing of information-bearing signals. Signal processing is responsible for switching and routing traffic, establishing links, restoring broken links, and monitoring and managing the network.

45.1.1 Signal Processing in Optical Networks

At present, the important and functionally complex signal-processing operations of switching and routing are carried out electronically. Electronic signal processing imposes two significant limitations on the functionality of optical networks: cost and opacity. Signal switching and routing requires conversion of the optical information into electrical signals, processing in the electronic domain, and converting back to the optical domain before retransmission. Such an operation requires detection, retiming, reshaping, and regeneration at each switching and routing point. This necessitates complex and expensive electronic and electro-optical hardware at each routing and switching node. The use of electronic signal processing places strict requirements on the format of data streams transferred and processed, thus making the signal processing opaque. Repetition rates of optical signals, power levels, and packet lengths have to be standardized before they can be processed electronically.

The ability to perform signal processing operations entirely within the optical domain would eliminate the requirement for optical–electrical–optical conversions, while providing agility and speed inherent to optical elements. Optical signal processing, in contrast with electronics, may provide ultrafast sub-picosecond switching times [45.3].

45.1.2 Optical Signal Processing Using Nonlinear Optics

Nonlinear optics can potentially support ultrafast self-processing of signals.

A variety of nonlinear optical signal-processing functions can be realized with similar fundamental building blocks [45.4–6]. Nonlinear optical elements and devices can be either integrated in photonic circuits [45.7] or used in a free-standing configuration [45.8]. Nonlinear optics can enable signal processing without the requirement for external electrical, mechanical, or thermal control [45.9]. The response time of properly designed nonlinear optical devices is limited fundamentally only by the nonlinear response time of the constituent materials [45.3, 10–12].

Photons do not interact with each other in vacuo. In order to perform nonlinear optical signal-processing operations the properties of a medium through which the light travels must be modified by the light itself. Optical signals then propagate differently as a result of their influence on the medium. Nonlinear optical signal-processing elements utilize the illumination-dependent

real and imaginary parts of the index of refraction [45.9]. Depending on the material and spectral position, the real part of the refractive index and absorption of a given nonlinear material can either increase or decrease with increasing illumination.

A wide range of broadband and wavelength-selective nonlinear optical signal-processing devices has been proposed and demonstrated.

The most commonly studied nonlinear optical switching elements are nonlinear Fabry–Perot interferometers, nonlinear Mach–Zehnder modulators, nonlinear directional couplers, optical limiters, and nonlinear periodic structures.

A nonlinear Fabry–Perot interferometer consists of two mirrors separated by a nonlinear material. As the refractive index of the nonlinear material changes with an increased level of illumination, the effective path length of the resonator is altered. A nonlinear Fabry–Perot interferometer can be tuned out of, or into, its transmission resonance. When illuminated with the continuous-wave light, a nonlinear Fabry–Perot interferometer can exhibit optical bistability. Optical bistability is a phenomenon in which the instantaneous transmittance of the device depends both on the level of incident illumination and on the prior transmittance of the device. Such an element enables all-optical memory.

In a nonlinear Mach–Zehnder modulator and a nonlinear directional coupler, a part of the waveguide is made out of a nonlinear material. Changing the intensity of the incident light changes the effective path length experienced by the light. This, in turn, through phase interference, results in an illumination-dependent transmittance in a Mach–Zehnder modulator, and an illumination-dependent coupling in a nonlinear directional coupler.

A number of techniques use nonlinear properties of materials to obtain power-limiting, and associated with it, on–off switching. Such devices are based on total internal reflection [45.13], self-focusing [45.14], self-defocusing, two-photon absorption [45.15], or photorefractive beam fanning [45.16].

Nonlinear periodic structures combine the phenomena of nonlinear index change and distributed Bragg reflection. The intensity-dependent transmission and reflection properties of nonlinear periodic structures can be harnessed to yield various signal-processing functions. It has been demonstrated that nonlinear periodic structures can support optical switching and limiting [45.4–6, 17–20], optical bistability [45.8, 21–25], solitonic propagation of pulses [45.26, 27], and pulse compression [45.28].

45.1.3 The Approach Taken During this Survey of Nonlinear Optoelectronic Materials

There exist excellent texts that describe nonlinear optical processes and review the published properties of nonlinear materials [45.29–35]. This chapter will discuss the applicability of different material groups to non-

linear optical switching. Following the introduction of the concept of nonlinear refractive index and figures of merit in Sect. 45.2, the nonlinear properties of inorganic crystalline semiconductors (Sect. 45.3), organic materials (Sect. 45.4), nanocrystals (Sect. 45.5), and selected other materials (Sect. 45.6) will be reviewed and summarized. A critical review is given with a focus on figures of merit and processability.

45.2 Illumination-Dependent Refractive Index and Nonlinear Figures of Merit (FOM)

In a nonlinear optical medium intense light alters the real and imaginary components of the refractive index. The nonlinear response of the real part of the refractive index modifies the phase of propagating light, while the imaginary part describes the change in absorption.

This subsection will present the formalism used to describe how light affects the ultrafast and resonant changes in the nonlinear refractive index. The ultrafast nonlinear index changes take place in the spectral region where the material is nonabsorbing, while the resonant nonlinear index changes take place in the absorbing spectral region.

45.2.1 Ultrafast Response

Ultrafast nonlinear response is characterized by the instantaneous response, weak nonlinear index changes, and weak nonlinear absorption. The formalism that describes the ultrafast changes in the real and imaginary parts of the refractive index can be derived from the theory of nonlinear polarization.

The polarization $\mathbf{P}(r, \omega)$ of a material in the presence of an electric field $\mathbf{E}(r, \omega)$ at a frequency ω and position r is defined as

$$\mathbf{P}(r, \omega) = \epsilon_0 \chi(r, \omega) \mathbf{E}(r, \omega), \quad (45.1)$$

where ϵ_0 is the permittivity of free space and $\chi(r, \omega)$ is the dielectric susceptibility tensor. $\chi(r, \omega)$ is related to the index of refraction $n(\omega)$ by

$$\chi(r, \omega) = n^2(r, \omega) - 1. \quad (45.2)$$

In a homogeneous nonlinear material $\chi(r, \omega) = \chi(\omega)$ but $\chi(\omega)$ is not constant with electric field and the influence of $\mathbf{E}(r, \omega)$ on $\mathbf{P}(r, \omega)$ is not linear. In this case it is customary to expand $\mathbf{P}(r, \omega)$ in a power series of

$\mathbf{E}(r, \omega)$ [45.34]:

$$\begin{aligned} \mathbf{P}(r, \omega) = & \epsilon_0 \chi^{(1)}(\omega) \mathbf{E}(\omega) \\ & + \epsilon_0 \left[D^{(2)} \sum_{j,k} \chi_{ijk}^{(2)}(-\omega_3; \omega_1, \omega_2) \right. \\ & \times \mathbf{E}_j(\omega_1) \mathbf{E}_k(\omega_2) \\ & + D^{(3)} \sum_{jkl} \chi_{ijkl}^{(3)}(-\omega_4; \omega_1, \omega_2, \omega_3) \\ & \times \mathbf{E}_j(\omega_1) \mathbf{E}_k(\omega_2) \mathbf{E}_l(\omega_3) \\ & \left. + \text{higher-order terms} \right], \end{aligned} \quad (45.3)$$

where $\chi^{(1)}$ is the linear susceptibility, while $\chi^{(2)}$ and $\chi^{(3)}$ are the coefficients of the second- and third-order nonlinear susceptibility. The coefficients $D^{(2)}$ and $D^{(3)}$ are defined as:

$$D^{(2)} = \begin{cases} 1, & \text{for indistinguishable fields} \\ 2, & \text{for distinguishable fields} \end{cases} \quad (45.4)$$

and

$$D^{(3)} = \begin{cases} 1, & \text{for all fields indistinguishable} \\ 2, & \text{for two fields indistinguishable} \\ 3, & \text{for all fields distinguishable} \end{cases} \quad (45.5)$$

In all known materials the higher-order components of the effective nonlinear susceptibility tensor $\chi(\omega)$ yield smaller contributions to the effective polarization than the preceding terms of the same parity. On the other hand, in the presence of strong electric field the terms designated as the *higher-order terms* in (45.3) [i. e. terms proportional to the powers of $\mathbf{E}(r, \omega)$ higher than four],

can be larger than the first three terms. However, the assumption of moderate intensities and the aim to illustrate the concept of nonlinear refractive index justifies retaining only the first three terms of (45.3) in the derivation that follows.

Nonlinear optical switching relies on nonlinear effects in which intense light changes the refractive index. Under such conditions there are no direct-current (DC) or low-frequency electro-optic effects present and the second term in (45.3) can be neglected. In addition all values of ω are degenerate. $\mathbf{P}(r, \omega)$ reduces to

$$\begin{aligned}\mathbf{P}(r, \omega) &= \epsilon_0 [\chi^{(1)}(\omega) + \chi^{(3)}(\omega) \mathbf{E}(\omega) \mathbf{E}(\omega)] \mathbf{E}(\omega) \\ &= \epsilon_0 \left[\chi^{(1)}(\omega) + \frac{2\chi^{(3)}(\omega) I}{\epsilon_0 n_0 c} \right] \mathbf{E}(\omega),\end{aligned}\quad (45.6)$$

where I is the local intensity

$$I = \frac{\epsilon_0}{2} n_0 c |E(\omega)|^2, \quad (45.7)$$

and c is the speed of light in vacuum.

The first term in (45.6) represents the linear contribution to the polarization and the second term represents the nonlinear, intensity-dependent part. This intensity-dependent part gives rise to the nonlinear index of refraction fundamental to this work.

To obtain the direct expression for the nonlinear refractive index the effective susceptibility from (45.6) is substituted into (45.2) to yield

$$n^2 = 1 + \chi^{(1)} + \frac{2\chi^{(3)}(\omega) I}{\epsilon_0 n_0 c}. \quad (45.8)$$

In order to relate directly this nonlinear part of polarization to the intensity-dependent part of the refractive index – a macroscopic measurable quantity – the effective index of refraction is expressed as

$$n = n_0 + n_2 I. \quad (45.9)$$

Taking the square of (45.9) and neglecting the terms proportional to I^2 under the assumption of weak relative nonlinearity ($n_2^2 I^2 \ll n_0 n_2 I$ and $n_2^2 I^2 \ll n_0^2$) gives

$$n^2 = n_0^2 + 2n_0 n_2 I. \quad (45.10)$$

Equating (45.8) and (45.10) gives an expression for n_2

$$n_2 = \frac{\chi^{(3)}}{\epsilon_0 n_0^2 c}, \quad (45.11)$$

where all the factors are in SI units.

In general, n_2 can have real (Re) and imaginary (Im) parts with $n_{2\text{Re}}$ responsible for the nonlinear refraction

and $n_{2\text{Im}}$ responsible for the nonlinear absorption or gain. There are many conventions used to express the real and imaginary parts of the nonlinear refractive index. The approach used by researchers must always be determined prior to comparison with absolute numbers. However, in general it is safe to write

$$n_{2\text{Re}} = \frac{K}{n_0^2} \text{Re}(\chi^{(3)}) \quad (45.12)$$

and

$$n_{2\text{Im}} = \frac{K}{n_0^2} \text{Im}(\chi^{(3)}), \quad (45.13)$$

where the constant K depends on the convention and units used [45.34].

In the rest of this chapter n_2 will be used to express the real part of the ultrafast nonlinear index of refraction, i.e. n_2 will be as used in (45.12).

In order to account for the imaginary component of the ultrafast nonlinear response in a commonly used way the following relationship is defined

$$\alpha = \alpha_0 + \beta I. \quad (45.14)$$

Equation (45.14) expresses the total absorption (α) in terms of its linear (α_0) and nonlinear (βI) contributions. β is the measurable, macroscopic quantity that will be used throughout this chapter to quantify the effects of the ultrafast imaginary nonlinear response.

45.2.2 Ultrafast Nonlinear Material Figures of Merit

A nonlinear material useful in a nonlinear optical signal-processing device must simultaneously satisfy the following conditions:

- The excitation time of the nonlinear effect must be less than the pulse width.
- The sum of the excitation and the relaxation times must be shorter than the pulse spacing.

In addition, an ultrafast nonlinear material must satisfy the following requirements:

- The effect of linear absorption must be weak compared to the effect of nonlinear refraction. *Stegeman* quantifies this condition in terms of the unitless figure of merit W [45.12]

$$W = \frac{|\Delta n|}{\alpha_0 \lambda} > 1, \quad (45.15)$$

where Δn is the induced change in the real part of the refractive index, α_0 is the linear absorption (expressed in units of inverse length) and λ

is the wavelength of light (with units of length). To facilitate consistent comparison between different nonlinear materials, Δn in (45.15) was assumed to be evaluated as the intensity approaches the saturation intensity, at which the rate of change of the refractive index drops noticeably below a linear dependence on intensity [45.12]. In general (45.15) can be used to quantify the nonlinear quality of a given material at any intensity, not only at the saturation.

- The effect of two-photon absorption must be weak compared to the effect of nonlinear refraction. This condition is quantified using the figure of merit T [45.12]

$$T = \frac{\beta_2 \lambda}{n_2} < 1, \quad (45.16)$$

where β is the two-photon absorption coefficient from (45.14) (expressed in units of length/power).

The conditions (45.15) and (45.16) can be combined in terms of a single figure of merit F

$$F = \frac{|\Delta n|}{\alpha_{\text{eff}} \lambda} > 1, \quad (45.17)$$

where α_{eff} is the effective absorption experienced by the sample at a given intensity. F can be used to quantify the quality of materials for signal processing with respect to nonlinear processes of any order rather than with respect to only third-order processes as in (45.16).

Condition (45.17) ensures that the nonlinear phase shift $\Delta\phi^{\text{NL}} = 2\pi\Delta nL/\lambda$, where L is the length of the material, reaches 2π before the intensity decays to $1/e$ of its input value as a result of the effective absorption. Phase shifts between 0.5π and 3.5π are required for most optical switching devices [45.12].

45.2.3 Resonant Response

The resonant response of a nonlinear material is the dominant nonlinear effect in the linearly absorbing spectral region. A different formalism than that presented in Sects. 45.2.1 and 45.2.2 is used to describe the resonant changes in the real and imaginary parts of the refractive index.

Illumination with light which is resonant with the material results in the direct absorption of the incoming photons, generating excited states and giving rise to a decrease in the effective absorption. If the relaxation time of the excited states is longer than the length of the pulse, the resonant effect is proportional to the

fluence, rather than to the intensity of the incident ultrafast pulse. This saturation of the absorption is described by the following expression for the effective absorption α_{eff} [45.35]

$$\alpha_{\text{eff}} = \frac{\alpha'_0}{1 + \frac{P}{P_{\text{sat}}}} + \alpha_u. \quad (45.18)$$

where α_u is the unsaturable absorption, $P = \int_0^t I(t') dt'$ is the incident fluence and P_{sat} is the saturation fluence at which the effective absorption decreases to half of its initial value $\alpha_0 = \alpha'_0 + \alpha_u$. P accounts for the cumulative (up to the duration of the pulse) character of the resonant nonlinear response.

The saturation of absorption is accompanied by a change in the real part of the refractive index [45.35]

$$\Delta n = \frac{n'_2 P}{1 + \frac{P}{P_{\text{sat}}}}. \quad (45.19)$$

n'_2 describes the strength of the real part of the resonant nonlinear refractive index.

In this chapter, nonresonant and resonant phenomena are considered. The parameters n_2 and β from Sect. 45.2.1 are used to quantify the ultrafast response and Δn and $\Delta\alpha$ from Sect. 45.2.1 are used to describe the resonant response.

45.2.4 Resonant Nonlinear Material Figures of Merit

Figures of merit for the nonresonant response have been defined in Sect. 45.2.2. This section will introduce resonant figures of merit that account for the nonlinear phase shift that accumulates over the duration of a pulse.

For illustrative purposes, first-order approximations to (45.18) and (45.19) of the form $\Delta n(t) = \int_0^t n'_2 I(t') dt'$ and $\alpha_{\text{eff}}(t) = \alpha_0$ are considered under the assumption $P \ll P_{\text{sat}}$. A resonant nonlinear material is assumed to be illuminated with a square pulse of the form:

$$I(t) = \begin{cases} I_0, & \text{if } 0 < t < \tau_p \\ 0, & \text{if } t > \tau_p. \end{cases} \quad (45.20)$$

In analogy to (45.17) a time-averaged nonlinear figure of merit is defined for the resonant response

$$\langle F \rangle = \frac{|\langle \Delta n \rangle|}{\langle \alpha \rangle \lambda}. \quad (45.21)$$

The time-averaged nonlinear index change is

$$\begin{aligned}\langle \Delta n \rangle &= \frac{1}{\tau_p} \int_0^{\tau_p} \left[\int_0^t n'_2 I(t') dt' \right] dt \\ &= \frac{n'_2 P_{\text{total}}}{2} = \frac{|\Delta n_{\text{peak}}^{\text{ultrafast}}|}{2},\end{aligned}\quad (45.22)$$

where P_{total} is the total fluence of the pulse $P_{\text{total}} =$

$\int_0^{\tau_p} I(t') dt' = I_0 \tau_p$. The time-averaged absorption is $\langle \alpha \rangle = \alpha_0$. For the case considered, the figure of merit (45.21) becomes:

$$\langle F \rangle = \frac{|\Delta n_{\text{peak}}|}{2\alpha_0 \lambda}, \quad (45.23)$$

which is half of the ultrafast figure of merit. For simplicity, (45.17) will be used throughout this chapter for both resonant and ultrafast response.

45.3 Bulk and Multi-Quantum-Well (MQW) Inorganic Crystalline Semiconductors

The illumination-dependent refractive and absorptive nonlinear properties of inorganic crystalline semiconductors have been studied comprehensively. Since semiconductors are at the heart of the electronics industry, semiconductor micro- and nanofabrication techniques are well established. This enables the preparation of high-quality nonlinear samples and devices. The ability to change the composition of semiconductor compounds allows the tuning of the electronic band gap over the visible and infrared spectral ranges. The spectral position of the band gap, in turn, tunes the nonlinear properties.

When a semiconductor is illuminated with light at a frequency within the absorbing region, the dominant nonlinear effect relies on the presence of linear absorption. Upon absorption of the incident light, the electrons undergo a transition from the valence band to the conduction band, saturating the absorption. This band-filling effect is accompanied by a very large change in the real part of the refractive index.

In a nonresonant nonlinear process no single-photon absorption takes place. Under illumination with intense light the electronic clouds of the constituent atoms are distorted, changing the refractive index of the material. Associated with this is a multiphoton absorption process which takes place when the sum of the photon energies is larger than the band-gap energy. This effect changes the absorption characteristics of the material. Both the real and imaginary parts of ultrafast nonlinear index change, given their connection through the nonlinear Kramers–Kronig relations.

In addition, when subjected to an intense continuous wave or a high-repetition-rate pulsed illumination, the temperature of the absorbing materials, including semiconductors, increases. This in turn changes the refractive index. Thermal effects have relaxation times as long as

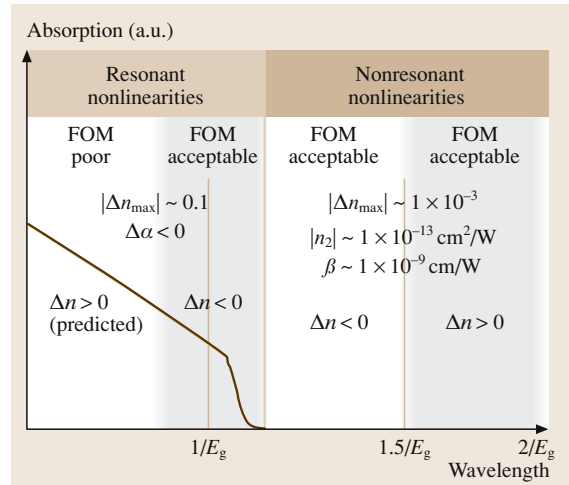

Fig. 45.1 Trends in the nonlinear response of bulk semiconductors

milliseconds and are not useful in processing trains of closely spaced pulses.

Figure 45.1 shows typical trends in the nonthermal nonlinear response of bulk inorganic crystalline semiconductor material under picosecond, low-repetition-rate illumination.

45.3.1 Resonant Nonlinearities

The two most important characteristics of the resonant nonlinear response are saturation of absorption and large nonlinear index change [45.36–38]. The relaxation of resonant nonlinear effects in semiconductors is not instantaneous. As long as the duration of the incident pulse is shorter than the relaxation time of the material, the magnitude of a nonlinear resonant response

is proportional to the fluence, rather than to the intensity of the incident pulse. The relatively long relaxation time of nonlinear effects in bulk and multi-quantum-well (MQW) inorganic crystalline semiconductors (from hundreds of picoseconds to tens of nanoseconds) is often used as an argument against using resonant nonlinearities. However, established techniques such as low-temperature growth and doping can reduce the relaxation time down to tens of picosecond [45.39, 40].

The phenomenon of saturation of absorption ($\Delta\alpha < 0$) translates into absorption that decreases with increasing incident fluence. Resonant figures of merit of semiconductors are acceptable near the band edge and become worse at lower wavelengths. Such behavior is due to a stronger, lower-threshold saturation of absorption around the band edge.

Nonlinear index change is negative around the band edge and has been predicted to be positive at wavelengths lower than those corresponding to the first heavy-hole and light-hole excitonic peaks.

Resonant Nonlinearities in Bulk Semiconductors

In 1991 Gupta et al. measured the time of nonlinear response of GaAs grown at low temperatures (LT-GaAs) [45.42]. Changes in reflectivity were monitored during a pump-probe experiment at 620 nm. Relaxation times of several 2- μm -thick samples grown at temperatures ranging between 190 °C and 400 °C were measured. A decrease in the decay time to 0.4 ps was recorded with decreasing growth temperatures. This short relaxation time is drastically lower than the typical value of nanoseconds for unannealed GaAs [45.42].

In 1993 Harmon et al. studied the dependence of the nonlinear relaxation time in LT-GaAs on annealing temperatures. A decrease in the relaxation time down to sub-picosecond values was observed with decreasing annealing temperatures [45.43].

In a number of papers published between 1994 and 1998, the group of Smith, Othonos, Benjamin, and Loka reported on a series of comprehensive experiments carried out on various LT-GaAs samples grown using molecular beam epitaxy (MBE). The dependence of the magnitude and the response time of nonlinear effects on the growth and annealing temperatures was studied. Very large negative nonlinear index changes were measured ($\Delta n_{\text{max}} = -0.13$) accompanied by a strong saturation of absorption [45.44]. The relaxation time was measured to decrease to a few picoseconds for samples grown at 500 °C [45.45]. The pump-probe measurements were carried out in the band-edge region at

Fig. 45.2 Results of the pump-probe measurements illustrating the time-resolved change in transmission for He-InGaAsP samples with different Be doping concentrations. (After [45.41] with permission)

wavelengths of 870–890 nm. The decreased response time was attributed to the fast decay of excited carriers to mid-gap states. These states are an effect of the LT growth [45.40].

In subsequent years another group of researchers studied the strength and dynamics of intensity-dependent response in InGaAsP doped with Be grown with He-plasma-assisted MBE. As illustrated in Fig. 45.2, sub-picosecond relaxation times were obtained [45.41]. The rapid decay was explained by a short lifetime of excited states due to the existence of mid-gap He and He-Be trap states. Again, large negative changes in the real part of the refractive index and strong saturation of absorption were observed [45.39].

Resonant Nonlinearities in Semiconductor Multi-Quantum-Wells

The nonlinear properties of semiconductor multi-quantum-wells (MQWs) are similar to those of bulk semiconductors [45.38, 46, 47]. The nonlinear response in MQWs around the band edge is stronger and begins at lower fluences than in bulk materials.

Compared with bulk semiconductors, semiconductor MQWs offer an additional degree of freedom in selecting their nonlinear properties. The effective electronic band gap of a given semiconductor MQW structure, and hence the dispersion of real and imaginary

parts of its linear and nonlinear refractive index, are influenced by two factors: the choice of the compositions of the constituent compounds and the well-to-barrier thickness ratio.

In 1982 Miller et al. reported on the measurements of resonant nonlinear properties of semiconductor MQWs. A very strong absorption saturation was noticed around the first excitonic peak in GaAs/AlGaAs MQWs. Based on these results a large refractive nonlinearity was deduced from the nonlinear Kramers–Kronig relation [45.48]. A theoretical paper followed, explaining the dynamics of transient excitonic nonlinearities [45.49]. A 20-ns excited-carrier relaxation time was predicted.

In 1986 Lee et al. measured the nonlinear saturation of the absorption of bulk GaAs and 29.9-nm GaAs/AlGaAs wells grown by molecular beam epitaxy. The measurement was performed using a monochromatic pump and a broadband probe over a 40-nm spectral range near the MQW band edge. Using the nonlinear Kramers–Kronig relation, large index changes of both signs were predicted. In MQWs, absorptive and refractive nonlinearities were enhanced compared to bulk GaAs. Index changes ranging from $\Delta n = -0.06$ to $\Delta n = 0.03$ were predicted in the samples analyzed [45.50].

This report was followed in 1988 by a study of nonlinearities around the band edge carried out by the

same research group [45.38]. The response of bulk GaAs was compared with that of three sets of GaAs/AlGaAs MQWs, with well thicknesses of 7.6 nm, 15.2 nm and 29.9 nm. Again, a strong saturation of absorption was measured and nonlinear index changes of both signs were predicted from the nonlinear Kramers–Kronig relation [45.51]. The magnitude of the change in the real part of the refractive index was predicted to increase with decreasing well size. The sign of the refractive nonlinearity changed at wavelengths slightly shorter than that corresponding to the first excitonic peak [45.38].

Since 1988 many results of research on the nonlinear properties of GaAs/AlGaAs MQWs have been reported by Garmire et al. In a series of papers, the saturation of absorption was studied in GaAs/AlGaAs MQWs grown by metalorganic chemical vapor deposition epitaxy. The nonlinear Kramers–Kronig relation was used to predict the associated change in the real part of the refractive index. Figure 45.3 shows the predicted enhancement of nonlinearity with decreasing well size and the change of sign near the excitonic peak. Attempts were made to use the illumination-dependent shift of Fabry–Perot fringes to estimate directly the negative nonlinear index change along the band edge. However, this approach was admitted to yield significant errors, with the Fabry–Perot technique sometimes giving a value of Δn at twice the magnitude predicted

Fig. 45.3a,b Spectra of GaAs/AlGaAs MQWs of three different well widths, measured at various incident intensities by pulsed pump at 1.52 eV: **(a)** absorption coefficient α ; **(b)** the change in the real part of the refractive index Δn . (After [45.46] with permission)

from the Kramers–Kronig relation [45.46]. In 1987 Fox et al. reported nonlinear measurements around the band edge of bulk GaInAs [45.52] and GaInAs/InP MQWs near wavelengths of 1.6 μm [45.53]. Full saturation of absorption was observed. The nonlinear index changes deduced from the nonlinear Kramers–Kronig relation were slightly larger than that observed in GaAs [45.35].

Recently Brzozowski et al. published results of direct picosecond measurements of nonlinear refractive-index change and nonlinear absorption in $\text{In}_{0.530}\text{Al}_{0.141}\text{Ga}_{0.329}\text{As}/\text{In}_{0.530}\text{Ga}_{0.470}\text{As}$ multi-quantum-wells in the range 1480–1550 nm. Large low-threshold nonlinear index changes were found: Δn of up to 0.14 with a figure of merit of 1.38 at a fluence of 116 $\mu\text{J}/\text{cm}^2$. The figure of merit F was greater than unity over much of the spectrum. The results are summarized in Fig. 45.4.

In 1996 Judawlikis et al. reported the decreased nonlinear relaxation time in LT-grown Be-doped InGaAs/InAlAs MQWs. Nonlinear relaxation times of a few tens of picoseconds were observed in a pump-probe experiment near the band edge. The nonlinear change in the real part of the refractive index was not reported [45.56].

A different approach to decrease the response times of band-edge nonlinearities of semiconductor MQWs was taken by the groups of White, Sibbet, and Adams. An electric current was applied to active InGaAsP/InP waveguides and the nonlinear optical response under electrical bias was studied. It was found that under

a forward bias the refractive nonlinear response was quenched. Under a reverse bias the nonlinear response was slightly reduced, but the initially long recovery time was reduced to 50 ps [45.57] and 18 ps in subsequent experiments [45.58]. Further, it was found that, when the waveguide was biased at transparency, the nonlinear coefficients of the semiconductor MQW waveguides were $n_2 = 4 \times 10^{-11} \text{ cm}^2/\text{W}$ and $\beta = 4 \times 10^{-9} \text{ cm}/\text{W}$, giving a combined figure of merit of $F = 7$ [45.59]. In all measurements the negative nonlinear index changes were measured to have magnitude smaller than $|\Delta n| < 0.001$ [45.60].

45.3.2 Nonresonant Nonlinearities in Inorganic Crystalline Semiconductors

Nonresonant nonlinearities are not triggered by direct electronic transitions due to single photons. Much weaker effects of distortion of electronic clouds and multi-photon absorption are responsible for nonresonant nonlinear response. Maximum nonresonant nonlinear index changes are of the order $|\Delta n_{\text{max}}| \approx 1 \times 10^{-3}$. Since in certain spectral regions a typical nonresonant Kerr coefficient is $n_2 \approx 1 \times 10^{-13} \text{ cm}^2/\text{W}$, the linear absorption is around 5 cm^{-1} , and the corresponding two-photon absorption coefficient is $\beta \approx 1 \times 10^{-9} \text{ cm}/\text{W}$, the figures of merit associated with nonresonant semiconductor nonlinearities can be acceptable.

The biggest advantage of nonresonant semiconductor nonlinearities is their sub-picosecond response time. The sum of the rise and relaxation times of nonresonant nonlinearity has been argued to be comparable to the orbital period of an electron in its motion about the nucleus, estimated to be around 10^{-16} s [45.29].

Depending on the spectral region, bulk and MQW inorganic crystalline semiconductors may exhibit either positive or negative refractive nonresonant nonlinearities. Under illumination with sub-nanosecond pulses at low repetition rates, the nonlinear index change is negative for wavelengths up to $1.5ch/E_g$, where ch/E_g is the wavelength corresponding to the band gap, and h is Planck's constant. Δn is positive for wavelengths longer than $1.5ch/E_g$ [45.37, 61]. In MQWs the spectral position of the sign change in Δn depends on the nanostructure of MQWs [45.62]. In 1993 Shaw and Jaros predicted through theory the dispersion of refractive nonlinearity in semiconductor MQWs and superlattices. They found that in MQWs the proximity of the spectral position of the Δn sign change to the band edge increases with increasing quantum confinement [45.62].

Fig. 45.4 Nonlinear index changes of 121 10-nm $\text{In}_{0.530}\text{Al}_{0.141}\text{Ga}_{0.329}\text{As}$ barriers and 120 5-nm $\text{In}_{0.530}\text{Ga}_{0.470}\text{As}$ wells grown on S-doped 001 InP wafer substrate. The inset shows the corresponding figures of merit. (After [45.54, 55])

Under nonresonant illumination with pulses longer than one nanosecond, there is no sign change in the refractive nonlinearity. The negative nonlinearity originating from two-photon absorption-induced free-carrier effects is much stronger than any positive third-order refractive effects at moderate and high intensities for $hc/E_g < \lambda < 2hc/E_g$. Consequently, the measured Δn is always negative in this spectral range [45.63].

The group of Sheik-Bahae and Van Stryland has authored several reports on the prediction of the spectral dependence of nonresonant nonlinearities in semiconductors. In 1985 Van Stryland et al. predicted trends in the absorptive ultrafast nonlinear response of semiconductors. An equation for the two-photon absorption below the band gap was derived and compared with experimental values. Dispersion of two-photon absorption is expected to mimic the dispersion of linear absorption; i. e. two-photon absorption is strong and relatively flat from the band gap to almost the midpoint of the band gap, at which point it goes to zero. Good agreement was obtained between experiment and theory for photon energies not in the vicinity of the band gap, with two-photon absorption coefficients of various semiconductors ranging from $\beta = 3 \times 10^{-9}$ cm/W to $\beta = 25 \times 10^{-9}$ cm/W [45.36].

In the ensuing years the same research group reported theory describing the spectral dependence of the real part of the ultrafast nonlinearity and compared it with experiments. The results are shown in Fig. 45.5. The magnitude of n_2 is largest near the photon energy corresponding to half of the band gap. Since, for wavelengths longer than that corresponding to half the band gap, two-

Fig. 45.5 Dispersion of the refractive nonlinearity of inorganic crystalline semiconductors in the transparent region. The points correspond to the experimental data explained in [45.37], while the lines are a fit to the theory. (After [45.37])

photon absorption vanishes, large figures of merit can be expected in these spectral region. In addition, n_2 was predicted to be positive for wavelengths longer than that corresponding to $0.75E_g$, and negative between $0.75E_g$ and E_g [45.37, 64]. A large discrepancy between theoretical and experimental results was observed near the band gap, where the theory drastically underestimated the strength of the refractive nonlinearity.

45.4 Organic Materials

Organic materials constitute another class of promising nonlinear materials. Organic materials exhibit significant nonlinearities across the visible and infrared spectral regions [45.65]. They are readily processable into thin-film waveguide structures [45.33, 66] and in general do not rely on a high degree of perfection in ordering or purity to manifest their desired properties. The molecules that make up organic materials provide a tremendous range of structural, conformational, and orientational degrees of freedom for exploration with the aid of novel synthetic chemistry. This permits flexible modification and optimization of linear and nonlinear properties [45.33].

As is the case with semiconductor nonlinearities, the nonlinear response of organic materials can be divided into resonant and nonresonant parts, occurring in the absorbing and transparent regions, respectively. The resonant nonlinearities are a result of a single-photon absorption, while the nonresonant nonlinearities arise as a result of perturbations of electronic clouds and multi-photon absorption.

Depending on the structure of the constituent molecules, organic materials may exhibit many absorption resonances and hence many spectral areas of different strength and sign of nonlinear response. Phenomena such as molecular reorientation and pho-

Fig. 45.6 Typical trends in the nonlinear response of organic materials with one absorption resonance

toisomerization, which are often found in organic materials, make the picture even more complex.

Some organic materials, such as most nonlinear dyes, have only one absorption resonance, which permits the qualitative prediction of their nonlinear response in the visible and near-infrared regions. Fig. 45.6 shows the nonlinear response of a typical nonlinear organic material with one absorption resonance.

In general, the figures of merit of organic materials in the absorbing region are poor. However, molecular effects such as *trans*–*cis* photoisomerization strongly increase the nonlinear index change along the absorption edge. The magnitudes of ultrafast nonlinearities and associated figures of merit of organic materials are comparable to those of inorganic crystalline semiconductors.

45.4.1 Resonant Nonlinear Response of Organic Materials

Since 1998 *Rangel and Rojo* et al. have reported resonant nonlinear properties of various organic compounds. The nonlinear refraction and absorption effects were reported in and near the absorbing regions of: solid-state PMMA samples doped with nonlinear azobenzene dye Disperse Red 1 [45.67], polydiacetylene microcrystals in aqueous suspension [45.68], cyclohexane suspensions of vanadium-oxide phthalocyanine microcrystals [45.69, 70], solid-state samples of polythiophene/selenophene copolymer [45.71], and a chloroform solution of triazole-quinone derivation [45.72].

PMMA films doped with Disperse Red 1 (10% molar concentration) have been shown to exhibit large,

low-threshold nonlinear index changes and saturation of absorption as a result of optically induced structural changes in the middle and near the edge of the absorption resonance at 490 nm [45.67]. The nonlinear index changes associated with this photochemical phenomenon, called *trans*–*cis* photoisomerization have exceeded 0.1 in the spectral region $\lambda < 590$ nm. As illustrated in Fig. 45.7 [45.67], light near the main absorption resonance causes the azobenzene molecule to change from the *trans* to the *cis* configuration. During this process, the distance between the two carbons from which the acceptor and donor groups extend reduces from about 9.0 Å to 5.5 Å. This results in a drastic reduction in the molecule's dipole moment, which reduces the material's polarizability, providing a large negative nonlinearity with nonlinear index changes reaching $\Delta n_{\text{max}} = 0.12$ at 560 nm under illumination with 20-ps pulses at a repetition rate of 10 Hz [45.67]. The figures of merit calculated according to (45.17) did not exceed 0.42 over the spectral range studied.

The refractive and absorptive nonlinear properties of polydiacetylene microcrystals in aqueous solution have been analyzed across their absorbing and near resonance regions 500–800 nm [45.68] with the same system as in [45.67]. As shown in Fig. 45.8, both negative and pos-

Fig. 45.7 Chemical structure of the azobenzene dye Disperse Red 1 undergoing *trans*–*cis* photoisomerization. Following resonant absorption, the azobenzene molecule changes its configuration, resulting in a decreased dipole moment. (After [45.67] with permission)

Fig. 45.8 $\chi^{(3)}$ and linear absorbance as a function of wavelength for 100-nm polydiacetylene microcrystals. (After [45.68])

itive nonlinear index changes were observed, depending on the spectral position relative to one of the two absorption resonances in the visible region. Saturation of absorption was observed across the entire absorbing region. A three-level model was developed to explain the data. Because of the low concentration of microcrystals in water, the absolute values of the nonlinear index change did not exceed 2×10^{-4} , while the figures of merit stayed below 0.26.

Cyclohexane suspensions of vanadium-oxide phthalocyanine microcrystals have also been characterized around its main absorption resonance peak in the spectral range 600–680 nm [45.69, 70]. Similarly to the nonlinear response of polydiacetylene microcrystals, both signs of refractive nonlinearity were observed, with the sign of the nonlinearity tracing the derivative of the linear absorption. Solid-state samples of polythiophene/selenophene copolymer were analyzed near the absorbing region and have shown only negative nonlinearity [45.71]. These results contradicted the predictions from nonlinear Kramers–Kronig transformation, which predicts positive nonlinearity in the spectral region where absorption increases with wavelength. The origins of this discrepancy were not understood.

In 1997 Demenicis et al. reported on the measurements of nonlinear properties of poly(3-hexadecylthiophene) in a chloroform solution around the absorption edge of 532 nm with 70-ps pulses at a repetition rate of 5 Hz [45.73]. Saturation of absorption and negative nonlinearity was observed. The saturation intensity decreased with increasing concentration, while the nonlinear absorption and nonlinear refraction at low

intensity increased linearly. Figures of merit were not given.

45.4.2 Nonresonant Nonlinear Response of Organic Materials

In the 1970s it was predicted from theory and experimentally demonstrated that the conjugation of organic molecules results in a strong electronic delocalization and an associated large third-order nonlinearity in the transparent spectral region. This region extends between the main absorption peak due to the band-to-band transition and the first of the vibronic modes of the conjugated chain [45.74, 75]. It was demonstrated that the solid-state polymerization of organic monomers results in $\chi^{(3)}$ values comparable to these observed in inorganic crystalline semiconductors. Numerous studies followed that concentrated on the determination of the length and bond order of the conjugation chain, and acceptor and donor strengths that yield the strongest nonlinear response. Marder et al. provide an excellent summary of the field of nonresonant nonlinear response of organic molecules in [45.76].

Single-crystal polydiacetylene para-toluene sulfonates (PTS) have received special attention among the organic nonlinear compounds. In 1994 Lawrence et al. reported that at 1600 nm PTS has a large nonlinear refractive index of $n_2 = 2.2 \times 10^{-12} \text{ cm}^2/\text{W}$ [45.77]. Since linear absorption of PTS is very low at this wavelength, and two-photon absorption was below experimental sensitivity ($\beta < 0.5 \text{ cm}/\text{GW}$), and very large figures of merit were predicted with W exceeding unity for incident intensities as low as $20 \text{ MW}/\text{cm}^2$, and T never exceeding 0.1. A report followed in which Lawrence et al. showed measured two-photon absorption and nonlinear refraction values of PTS in the spectral range 800–1600 nm [45.78]. The two-photon-absorption coefficient varied in the range $0\text{--}700 \text{ cm}/\text{GW}$ while the measured n_2 coefficient was between $n_2 = -2.2 \times 10^{-12} \text{ cm}^2/\text{W}$ and $n_2 = 4.3 \times 10^{-12} \text{ cm}^2/\text{W}$. In 2000 and 2003 Yoshino et al. published two reports where the influence of three- and four-photon absorption on the nonlinear response was studied in the near-infrared region [45.79, 80]. For wavelengths of 1600–2200 nm the nonlinear refraction coefficient n_2 was around $n_2 = 5 \times 10^{-13} \text{ cm}^2/\text{W}$ while nonlinear absorption was dominated by three- and four-photon effects.

Although PTS exhibits nonlinear refractive-index changes and figures of merit that are very large for non-

linear material in the transparent region, **PTS** suffers from low processability – as a single-crystal it cannot be easily processed into desired shapes.

Third-order nonresonant nonlinear properties of fullerene organic compounds have also attracted significant attention [45.81, 82]. Recently *Chen et al.*

reported nonlinear coefficients and figures of merit of high-quality polyurethane films heavily loaded with (60)fullerene (C_{60}) [45.83]. Nonlinear refractive coefficients in excess of $10^{-12} \text{ cm}^2/\text{W}$ were reported in the wavelength range 1150–1600 nm with very good figures of merit.

45.5 Nanocrystals

Nanoscale quantum-confined inorganic crystalline semiconductors represent an interesting group of nonlinear materials [45.84]. The size of such quantum dots is less than the bulk radii of excitons, holes, and electrons in a given semiconductor. As in the case of semiconductor **MQWs**, this results in quantum confinement of carriers. In a nanocrystal, this takes place in all three dimensions [45.85, 86]. Quantized energy levels make nanocrystals an artificial analogue of noninteracting atoms in a gas, raising the possibility of explaining the nonlinear processes by adopting the models of atomic physics.

To allow processability nanocrystals are usually embedded in either solid or liquid, organic or glass, optically linear hosts. Nanocrystal material systems are thus hybrids of semiconducting and insulating materials and combine interesting properties from both material groups. As in the case of semiconductor **MQWs**, the composition and size of quantum dots determines the energy of the electronic transitions. This allows spectral

tunability of absorption features and nonlinear properties over the entire visible and infrared spectrum. On the other hand, the organic or glass host permits flexible fabrication of samples, waveguides, and other integrated components using polymer photonics technologies [45.87].

Figure 45.9 shows the properties of a typical resonant and nonresonant nonlinear response of strongly confined semiconductor nanocrystal composites. The data presented in this figure are based on the published theoretical predictions and experimental reports.

The finite number of allowed lower electronic levels leads to more pronounced excitonic features and resonant nonlinearities, which take place at lower fluences than in bulk or **MQW** inorganic crystalline semiconductors [45.88].

Similarly to the nonlinear response of bulk and **MQW** semiconductors, the resonant nonlinear response of nanocrystals is characterized by the saturation of absorption and an associated large change in the real part of the refractive index.

Saturation of absorption in strongly confined PbS quantum-dot glasses was measured in the spectral range 1.2–1.3 μm [45.89], covering the spectral position of the valley between the first and second excitonic peaks in the 6.6-nm-diameter sample studied. This material system was used as a passive saturable absorber in the production of 4.6-ps pulses via mode-locking around a wavelength of 1.3 μm [45.89]. The report was followed by studies of saturation of absorption dynamics in quantum dots of various sizes at a wavelength of 1.3 μm . This wavelength covered spectral regions ranging from the first to second electronic transitions, depending on the size of nanocrystals. The saturation energy and nonlinear decay times at a given wavelength were found to decrease with increasing size of nanocrystals [45.90]. Values for the refractive nonlinearity were not reported.

Saturation of absorption in PbS quantum-dot-doped glasses was also studied under illumination with 70-ps and 15-ns pulses 1.06 μm [45.91]. The

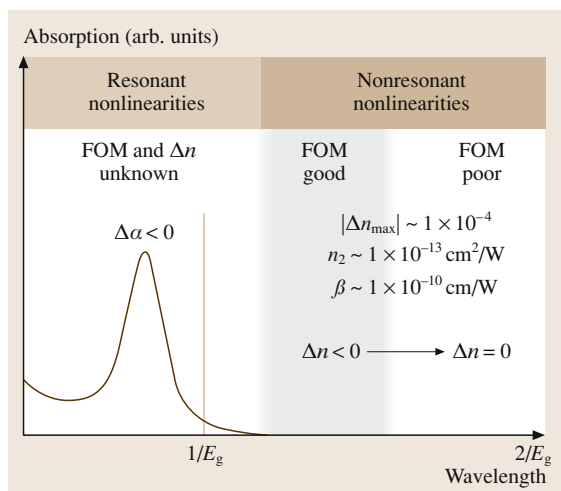

Fig. 45.9 Trends in the picosecond nonlinear response of inorganic semiconductor nanocrystals

nanocrystals analyzed had mean radii of 1.7–2.7 nm, resulting in excitonic peaks at wavelengths in the range 1.0–1.5 μm . The saturation intensity of the for the samples analyzed was found to be 2.3 MW/cm² and the relaxation time was measured to be 23 ± 2 ps.

Lu et al. measured the resonant nonlinear refractive properties of strongly confined 3.3-nm-diameter PbS nanocrystals in polymeric coatings over the spectral range 580–630 nm. This spectral range corresponds to the wavelengths around the first excitonic peak. The degenerate four-wave-mixing technique was used to measure the nonlinear susceptibility of nanocrystals near the photon energy of the first electronic transition at 595 nm. The values were found to fall in the range $\chi^{(3)} = 1 \times 10^{-6} - 1 \times 10^{-5}$ esu. Combined with the 50 kW/cm² intensity used in the experiment these values of $\chi^{(3)}$ suggest maximum nonlinear index changes of $\Delta n \approx 0.013$. No data on saturation of the absorption were reported.

The nonresonant nonlinear response of nanocrystals shows different dispersion characteristics than that of any other material group. Under illumination with picosecond pulses, the nonresonant third-order nonlinearity is negative for photon energies between half the band gap and the band gap [45.92]. The magnitude of

the third-order nonlinear response increases with proximity to the band gap, and disappears entirely near the half-band-gap energy. Such a response is in contrast to the Δn sign change between absorption and two-photon absorption resonances as observed in bulk semiconductors and organic materials. However, similarly to the nonresonant response of bulk semiconductors, the sign of the nonresonant refractive nonlinearity in the semiconductor-doped glasses in some spectral regions depends on the duration of the pulses used to measure the nonlinear effect. For pulses shorter than 1 ps the contribution of third-order positive refractive effects is comparable to that of the negative free-carrier absorption nonlinearities of the fifth order. Consequently, the measured Δn can be positive [45.63].

In 2000 and 2001 Liu et al. published several reports on measurements of the ultrafast nonlinearities of PbS nanoparticles, and PbS-coated CdS nanocomposites [45.93–95]. Surprisingly large refractive nonlinear indices of refraction up to -5×10^{-12} cm²/W and unmeasurable nonlinear absorption were observed in surface modified polymer–PbS composites at moderate concentrations of 1.9×10^{-3} mol/l. This large refractive nonlinearities were attributed to the surface recombination owing to the high surface-to-volume ratio of PbS nanoparticles.

45.6 Other Nonlinear Materials

Metallic nanocomposites and cascaded second-order materials are two other promising groups of nonlinear materials. Metalorganic nanocomposites are made out of metallic quantum dots embedded in organic or glass hosts. Resonant nonlinear properties of copper [45.96] and silver nanoparticles [45.97, 98] embedded in a glass host were measured using degenerate four-wave-mixing experiments at visible wavelengths. The nonlinear coefficients and figures of merit of the metallic nanocrystals characterized were similar to those of semiconductor nanocrystals and reached a maximum near the plasma-frequency absorption peak.

It has been argued that metallic nanoparticles can potentially exhibit stronger nonlinear effects than other

material systems [45.99]. This is associated with local field effects that enhance nonlinear response of the composite systems if the refractive index of the nonlinear constituent is lower than that of the linear host. Such a scenario can be realized in metallic nanoparticle–glass composites, since around the spectral positions of the plasma resonance the refractive index of metals can be lower than 1.

Cascaded nonlinear materials are made out of materials with second-order nonlinear properties. An appropriate design of such structures design results in a net accumulated phase shift for the illumination at a fundamental optical frequency at the end of a cascaded system. Cascaded material system acts as an effective third-order nonlinear material [45.100–102].

45.7 Conclusions

Following the preceding review, this section will summarize the major conclusions, as well as the missing pieces, of the published literature on nonlinear optical materials.

Bulk and MQW semiconductors have been demonstrated to exhibit low-threshold saturation of absorption near the band edge. The spectral position of the band edge can be tuned over the entire visible and near-infrared spectrum. It has been predicted from the nonlinear Kramers–Kronig relation, and has been measured directly in isolated cases, that the band-edge saturation of absorption results in large changes of the real part of refractive index.

In the regions of transparency, semiconductors exhibit weak nonlinear refractive effects of both signs. The nonresonant effects can be accompanied by two-photon absorption. Depending on the spectral position, the nonresonant nonlinear response of semiconductors can be characterized by good figures of merit.

Semiconductor nanocrystals also permit spectral tunability of their linear and nonlinear optical properties over the entire visible and near-infrared regions. Semiconductor nanocrystals have been demonstrated to exhibit strong saturation of absorption near the excitonic peak associated with the first allowed elec-

tronic transition. The nonresonant nonlinear response of nanocrystals is of a similar magnitude as in bulk and in MQW inorganic crystalline semiconductors.

The figures of merit for organic materials in the absorbing region are in general poor. In the transparent region the Kerr and two-photon absorption coefficients of organic materials are of magnitudes comparable to these of inorganic crystalline semiconductors. The sign of the refractive nonlinearity varies across the spectrum depending on the proximity to various absorption resonances.

Although the nonlinear properties of many materials systems have been reported, further characterization is needed to assess the applicability of various nonlinear material systems to optical signal processing. In contrast to previously reported measurements carried out at isolated wavelengths, measurements of the refractive and absorptive nonlinear response over wide spectral ranges, which would permit determination of figures of merit, need to be carried out. In particular, the refractive and absorptive nonlinear response in the most-promising absorption-edge regions of MQW semiconductors and semiconductor nanocrystals should be examined comprehensively and the applicability of these material systems to optical signal processing should be determined.

Solar Cells and Photovoltaics

Photovoltaic solar cells are gaining wide acceptance for producing clean, renewable electricity. This has been based on more than 40 years of research that has benefited from the revolution in silicon electronics and compound semiconductors in optoelectronics. This chapter gives an introduction into the basic science of photovoltaic solar cells and the challenge of extracting the maximum amount of electrical energy from the available solar energy. In addition to the constraints of the basic physics of these devices, there are considerable challenges in materials synthesis. The latter has become more prominent with the need to reduce the cost of solar module manufacture as it enters mainstream energy production. The chapter is divided into sections dealing with the fundamentals of solar cells and then considering five very different materials systems, from crystalline silicon through to polycrystalline thin films. These materials have been chosen because they are all in production, although some are only in the early stages of production. Many more materials are being considered in research and some of the

more exciting, polymer and dye-sensitised cells are mentioned in the conclusions. However, there is insufficient space to give these very active areas of research the justice they deserve. I hope the reader will feel sufficiently inspired by this topic to read further and explore one of the most exciting areas of semiconductor science. The need for high-volume production at low cost has taken the researcher along paths not normally considered in semiconductor devices and it is this that provides an exciting challenge.

Photovoltaic (PV) devices are a method of converting radiant solar energy into electrical energy. Most of our energy sources, including fossil fuels, hydroelectric and wind power actually come from solar radiation but are indirect conversions into electricity. Another class of solar energy conversion is the heating of water in solar thermal panels. Although the conversion efficiency can be high, they do not generate the thermal energy necessarily where and when it is needed, so storage is required. Direct generation of electric energy is attractive because it is a versatile energy form, rapidly converted into heat, mechanical or light energy. Photovoltaic energy is the main source of energy in the rapidly expanding satellite market with high-efficiency photovoltaic modules producing more than 1 kW of power. Terrestrial applications are also rapidly growing with an estimated total installed capacity worldwide over 1 GW in 2004, increasing annually by 30–40%. This, how-

ever, is tiny compared with the total amount of electrical energy consumed each year, around 0.1% of primary energy demand. However, solar energy is very attractive as it is completely non-polluting and can help to reduce the amount of fossil fuels that we burn to generate electricity. World CO₂ emissions have grown by 8% since 1990. Any contribution from non-fossil-fuel alternatives such as solar energy will help to reduce this annual burden of CO₂ emissions that is now a widely accepted cause of global warming. So how much solar energy is available for conversion to electricity? The total solar energy falling on the Earth's surface each year is huge and 10 000 times the current consumption of energy. We only need to capture a tiny fraction of this to make a major contribution to our electricity supply but this will mean incorporating solar electric panels into most buildings; to achieve this it will need to be much cheaper to compete with current fossil-fuel electricity generation.

The range of applications outlined here place different demands on the design of the photovoltaic module and hence the materials solutions may well be different. Cost has already been mentioned as paramount for terrestrial power requirements, but for space applications resistance to ionising radiation is important. This section will consider the materials implications of competing technologies and how well they meet the criteria for different applications. The first section will deal with how a photovoltaic cell operates and introduce the

figures of merit that are used to compare photovoltaic cells and relate performance to theoretical performance. Solar-cell technology is promoted as a clean fuel technology which does not introduce CO_2 and pollutants into the atmosphere. However, for this to be a truly environmentally friendly technology, the manufacturing and eventual disposal will also have to be environmentally safe and this depends on the materials used and the fabrication technologies. These factors will be considered for each material system.

46.1 Figures of Merit for Solar Cells

In this section we will consider the operation of a photovoltaic cell and the significant parameters that characterise its performance. The objective of a photovoltaic cell is to capture as much of the solar energy as possible and convert this into electrical energy. The solar energy reaching the Earth's atmosphere fits a black-body distribution for a body at 5800 K. This spectrum becomes highly structured, particularly in the infrared part of the spectrum, by absorption bands due to atmospheric gases. By the time the solar radiation reaches the Earth's surface, it no longer fits a black-body distribution [46.1]. The shift in the spectral distribution will obviously affect the efficiency of absorption of the solar radiation, particularly considering that all semiconductor materials will display a cut-off wavelength dictated by the band gap of the semiconductor. It is necessary to specify the atmospheric absorption when quoting efficiency, as the depth of atmosphere that the solar radiation has passed through will affect both the spectral distribution and the total amount of energy. The measurement used is air mass (AM) and is defined as zero for solar radiation outside the atmosphere and 1 for radiation reaching the ground when the sun is at its zenith. For shallower angles the solar radiation has to penetrate a larger depth of atmosphere and the AM is therefore going to be greater than 1. For space applications AM 0 is the appropriate condition and for terrestrial applications (depending on the position on the Earth) AM 1.5 is a typical value quoted, which corresponds to a solar angle of 45° . All this assumes that there is no cloud cover, which will further reduce the integrated intensity and modify the solar spectrum. Although cloud cover will reduce the amount of solar energy available for conversion, useful amounts of electricity can still be generated.

The available solar energy also decreases from 1353 W/m^2 outside the atmosphere (AM 0) to 925 W/m^2 for AM 1, when the sun is directly over-

head. In practice, for terrestrial applications the available solar energy is considerably less than this where, in general, $\text{AM} > 1$ and is further reduced by cloud cover.

A photovoltaic cell is basically a diode with a photogenerated current. A band diagram is shown schematically in Fig. 46.1. Absorption of radiation can occur on both sides of the junction, creating minority carriers that can diffuse towards the junction. A photocurrent is generated if the minority carriers can drift across the junction without recombination. In practice, the junction is shallow and absorption will occur predominantly on one side where there is a greater depth of absorbing material. There are also heterojunction p-n devices where less absorption will occur in the wider-band-gap layer, as shown in Fig. 46.2. So, one side of the junction is considered to be the absorber layer and it is the spectral absorption characteristics of this layer that

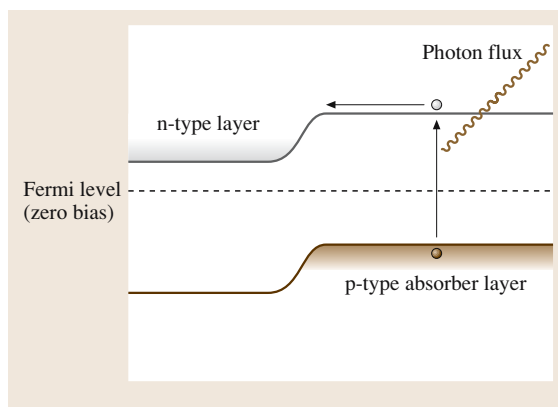

Fig. 46.1 Schematic of an energy-band diagram for a p-n junction solar cell showing photoabsorption to create an electron-hole pair and diffusion of the electron towards the junction

Fig. 46.2 Band diagram for a heterojunction PV cell showing illumination through the wide-band-gap window layer

Fig. 46.3 Ideal J - V characteristic for a photovoltaic cell, according to (46.1) with J_s equal to 30 mA/cm^2 . The parameters J_{sc} and V_{oc} are indicated on the graph. The maximum extracted power is shown as the shaded area

will determine the maximum absorption possible from the available solar radiation.

An ideal diode characteristic for an illuminated cell is shown in Fig. 46.3. In the dark the J - V plot would go through the origin and, as the light intensity increases, the short-circuit current becomes increasingly negative, indicating the presence of a photogenerated current. The equation for the J - V characteristic of this ideal device is:

$$J = J_s \left(e^{qV/k_B T} - 1 \right) - J_L, \quad (46.1)$$

where J_s is the saturation current in reverse bias under zero illumination, q is the charge on the carrier, V

is the applied voltage, k_B is Boltzmann's constant, T is the temperature of the cell and J_L is the photogenerated current. In the ideal cell this is equal to the short-circuit current, indicated as J_{sc} on the J - V curve in Fig. 46.3. Power can be extracted from the device in the $+V$, $-J$ quadrant of the J - V plot and the load will determine the operating point in this quadrant. The power is determined from the product JV at this operating point, shown graphically in Fig. 46.3. The maximum power will correspond to the operating point that will give the largest JV area on this graph. For the ideal diode characteristics given in (46.1), this maximum power is given by the following (46.2):

$$\begin{aligned} P_m &= I_m V_m \\ &= I_L \left[V_{oc} - \frac{k_B T}{q} \ln \left(1 + \frac{q V_m}{k_B T} \right) - \frac{k_B T}{q} \right] \\ &= I_L (E_m/q), \end{aligned} \quad (46.2)$$

where E_m is the maximum energy that can be extracted per photon and depends on the band parameters for the semiconductor absorber layer, which determine V_{oc} and V_m . These parameters are marked on the J - V plot in Fig. 46.3. We now have two fundamental parameters which will limit the efficiency of the cell:

- The fraction of solar photons absorbed in the cell.
- The electrical energy created per photon.

The first factor can be calculated by integrating over the solar spectrum for the appropriate AM number and including the cut-off wavelength of the semiconductor absorber layer.

$$\eta_{\text{abs}} = \frac{\int_{E_g}^{\infty} n_E(E) dE}{\int_0^{\infty} n_E(E) dE}. \quad (46.3)$$

This is shown graphically in Fig. 46.4 for AM 1.5. Any photons with energy less than the band gap will not be absorbed and will not contribute to the photocurrent.

The second efficiency factor mentioned above implies that not all the photon energy will be converted into electrical energy, even if one photon absorbed constitutes one minority carrier crossing the junction. The electrical energy per carrier is given by the factor E_m in (46.2), so the maximum power of the device is the product of the absorption rate of photons and the mean electrical energy created per photon. This product is represented by the inner shaded area of the solar spectrum shown in Fig. 46.4. The difference between curve 1 and

Fig. 46.4 Graphical representation of the maximum energy that can be extracted from a CdTe solar cell with a band-gap energy of 1.45 eV

curve 2 is simply the energy lost per photon because not all the photon energy is converted into electrical energy. Different semiconductor materials will have different efficiencies primarily because of different values for the band gap. The ideal value for E_m will track the band gap, so for narrower-band-gap materials there will be a larger proportion of photons absorbed but less electrical energy per photon. The function of efficiency for semiconductors with different band gap, taken from curve 2 in Fig. 46.4 is plotted in Fig. 46.5 and shows that the optimum efficiency occurs for semiconductors with a band gap in the near-infrared region, around 1.5 eV. This represents the best compromise between absorption of solar radiation and transferring the optimum amount of energy per photon into electrical energy.

The maximum efficiency is predicted for Si, InP, GaAs and CdTe, which are in the region of 30% for AM 1.5 irradiation (1 sun illumination). This means that the very best conversion efficiency for a single-junction cell is approximately one third of the available solar energy. In practice, photovoltaic cells have efficiencies considerably less than this due to optical reflections, poor junction characteristics and carrier recombination. These are materials issues that are often traded off against production costs, e.g. using polycrystalline

Fig. 46.5 Plot of ideal efficiency against band-gap energy for a single-junction cell for AM 1.5 illumination conditions, (after Henry [46.1])

rather than single-crystal material. Conversely, higher conversion efficiencies can be achieved using multiple junctions which are more expensive but attractive for space applications and when used in combination with solar concentrators, so less surface area of the expensive multijunction cell is required. Other factors that can influence the choice of photovoltaic materials include the following:

- absorption coefficient,
- contact resistance,
- abundance of raw materials,
- toxicity of materials,
- stability of materials and junctions,
- radiation resistance.

These factors will be considered in the following examples of different photovoltaic systems to assess the merits of different materials. It is probably true to say that there is not one ideal material but different applications can make one material more attractive than another.

46.2 Crystalline Silicon

Over 80% of the current world production of solar modules are made from either single-crystal or

multigrain silicon. This is the most mature of the photovoltaic materials and has benefited considerably

from the size of the silicon semiconductor industry. This has ensured a ready supply of material and processing tools suitable for large-scale production. However, crystalline silicon does suffer from a fundamental disadvantage in that the band gap of silicon is indirect, which means that the absorption coefficient is much lower than a direct-band-gap semiconductor such as CdTe. In practice this means that a much thicker piece of material is needed to absorb all the solar radiation greater than the band-gap energy. This requires wafers of silicon thicker than $100\text{ }\mu\text{m}$ and means that this material is not suitable for thin-film technology. The highest-performance solar electric modules are made from wafers of single-crystal silicon cut from Czochralski-grown crystals, up to 30 cm in diameter. This was originally developed on the back of the silicon electronics industry, but the rapid increase in production volume of PVs is now driving production of silicon crystals. The conversion efficiency for single-crystal PV modules is around 17% with the potential for increases in the near future to 20%.

Multicrystalline silicon involves the relatively cheap path of casting silicon ingots that are not seeded but produce a random grain size of the order of 1 cm across. The ingots are cast in blocks, larger than 100 kg, and then sliced into wafers $300\text{-}\mu\text{m}$ thick and with an area of up to 20 cm^2 . The grain boundaries cause these wafers to be mechanically weaker than the single-crystal wafers and they will typically be thicker. This causes some trade off in price. Each cell can be expected to contain grain boundaries, so loss of photogenerated charge at

the grain boundary can cause some loss of efficiency. Typical module efficiencies for multicrystalline silicon are currently around 15%.

The junction is formed by phosphorus implantation to form a p-n homojunction and contacted by printing of a metal grid, usually of a Ni–Au alloy. Patterning of the surface prior to implantation and contacting has achieved the highest efficiency cells by improving light collection [46.2]. Another recent innovation that has contributed to higher efficiencies is the ‘V’-groove or buried junction. This is shown schematically in Fig. 46.6 and entails the grooving of the p-type silicon substrate, implantation of phosphorus to create a buried junction and filling with metal contact alloy. This helps to improve the collection efficiency of the cell, particularly in the blue part of the spectrum. These manufacturing steps have to handle large volumes and be cheap. Cheaper alternatives to ion implantation involve thermal diffusion from a screen-printed paste or spin-on glass [46.3].

The main disadvantage of silicon is that the absorption coefficient is low because it is an indirect-band-gap semiconductor ($2 \times 10^3\text{ cm}^{-1}$ for Si compared with $1 \times 10^5\text{ cm}^{-1}$ for CdTe in the green part of the spectrum). This means that the amount of material needed to absorb the solar radiation is greater than for a direct-band-gap semiconductor. The absorption can be improved by having a reflecting back contact that, if it is roughened, will increase the mean path length of the back reflected light in the silicon cell. This is particularly important for thin-film silicon devices where the amount of material is more of an issue, although the thickness of $30\text{--}100\text{ }\mu\text{m}$ can be compared with the much thinner layers used for direct-band-gap semiconductors (see CdTe and GaAs).

Thin-film polycrystalline silicon is grown by ribbon casting techniques. The pulling speeds are in the range $10\text{--}1800\text{ cm/min}$, and this represents a cheap method for the production of solar cell material but the conversion efficiencies are currently low. One way of increasing the absorption coefficient is to deposit a film of amorphous silicon (a-Si), which has a similar band gap to crystalline silicon but is a direct-band-gap material. Amorphous silicon has led the way in cheap thin-film solar cells but suffers the disadvantages of low efficiency ($< 10\%$) and poor long-term stability. These cells will be discussed in greater detail in the next section.

Crystalline silicon solar cells, over the past 10 years, have approximately doubled in efficiency and this has been achieved by a combination of the

Fig. 46.6 Schematic of buried-contact technology for Si solar cells

following:

- Improved material quality, leading to improved minority-carrier diffusion length.
- Improved V_{oc} and fill factor through emitter and base doping and contact optimisation.
- Improved J_{sc} through diffusion length improvement using phosphorus gettering, hydrogen passivation and buried contacts.
- Surface passivation and contact grid optimisation.

All these aspects involve materials issues, either directly associated with the quality of the silicon or with contacting and passivation. It is also important to avoid degradation of the cell and the final encapsulation must avoid exposure of the cell to water. Multicrystalline sil-

icon can be passivated with silicon nitride deposited by plasma-assisted CVD from SiH_4 and NH_3 to reduce surface recombination [46.4].

Silicon solar modules are becoming cheaper to produce, nontoxic and stability in a non-radiation environment is good. Multicrystalline silicon is not so suitable for space applications because of the combination of thick absorber layers, requiring greater weight per unit area and the sensitivity of the cell to degrade in a high-radiation environment. However, single-crystal silicon competes well with GaAs cells in this market. Single-crystal modules for terrestrial applications produce the highest output powers currently available with a Sharp 1.3 m² module giving a peak output power of 185 W.

46.3 Amorphous Silicon

Amorphous silicon offers the potential for a cheap production technology for terrestrial photovoltaic solar cells. The amorphous state displays different physical properties to the crystalline with a modified band structure. One consequence of this is that the absorption coefficient in the green part of the visible spectrum is a factor of 10 higher at $2 \times 10^4 \text{ cm}^{-1}$, which makes it more suitable for thin-film applications. The amorphous structure leaves dangling bonds which pin the Fermi level and would normally prevent doping of the material. This is overcome by the inclusion of hydrogen, which passivates these dangling bonds, so the material is referred to as a-Si:H. The Si can also be alloyed with Ge, C, and N in a glow-discharge evaporator. These alloys are particularly useful for multijunction devices used for increasing the quantum efficiency. In the laboratory single-junction cells have efficiency around 8% with multijunction cells going up to 20%. In production an a-Si module has efficiency around 7%, considerably less than the crystalline materials.

The most common method for producing a-Si:H for photovoltaics is by plasma-enhanced CVD from SiH_4 mixtures. The films are deposited onto a textured conducting oxide such as indium–tin oxide (ITO) which provides the electrical contact and increases the average light path in the absorber layer to increase absorption. The device structure is a p-i-n with absorption taking place in the middle (insulator) layer, which is only 0.5 μm thick. The p and n layers can be deposited by adding B_2H_6 or PH_3 respectively to the plasma.

One of the major disadvantages of a-Si:H is the instability and long-term deterioration under light il-

lumination. This is caused by the rearrangement of dangling bonds, often associated with rearrangement of hydrogen atoms close to weak or dangling bonds. The energy comes from nonradiative bimolecular reactions and hence depends on the illumination intensity (for further details see the review by Bloss et al. [46.5]). In practice, this causes a downward drift in efficiency with time which can be as much as 2% in 100 h. The current cost is cheaper than crystalline silicon (3 US\$/Wp) but with the potential to considerably reduce cost to 0.7 US\$/Wp [46.6]. One of the main technical challenges is to maintain stabilised efficiency above 10%. The relatively high cost of PV solar modules compared with more conventional sources of energy can only become attractive if it can operate efficiently over a long period of time. This means that the modules must remain efficient over a period of 20 years. Shorter operating life times would have to be mitigated by much lower production cost.

In conclusion, a-Si:H is a low-cost technology for terrestrial applications and is finding its way into low-power applications such as small-scale stand-alone systems. With improved efficiency and stability s-Si has the potential to capture a significant proportion of the terrestrial market but the lower production costs are not sufficient to offset this at present. A typical a-Si module, with an area of 0.8 m², will have a peak output power of 40 W. The temperatures used in processing these modules is lower than the high temperatures needed to melt silicon for the crystalline silicon modules which means that the energy payback times could be just a few months.

46.4 GaAs Solar Cells

The III–V semiconductors have advantages over silicon due to their direct-band-gap photon absorption, with an absorption coefficient in the green of $8 \times 10^4 \text{ cm}^{-1}$. This means that, for example, GaAs can theoretically yield over 30% efficiency (AM 1.5) for an absorber layer thickness of just 1–2 μm , compared with a hundred times this for crystalline silicon. The efficiency, stability and thin-film deposition technology make these cells attractive for space applications. From Fig. 46.5 it is clear that the band gap of GaAs is well matched to the optimum for maximum efficiency. The III–V semiconductors also offer the flexibility of alloying to change the band gap and tune the response of the photovoltaic junction. In addition, heterojunctions can be formed and multijunction solar cells can be produced to convert more of the solar spectrum into electricity and thus exceed the theoretical limits set by the single-junction cells. For example, in the laboratory a GaAs/GaSb tandem solar cell has been reported with 35.6% efficiency [46.8]. Higher efficiencies are possible with three and even four junctions to capture more of the infrared that would otherwise not be absorbed. The Ge substrate, which is closely lattice matched with GaAs, can be used as a narrow-band-gap absorber to capture the radiation that passes through the GaInP₂/GaAs cell [46.7]. The top cell has an absorber of GaInP₂, which has a band gap of 1.9–2 eV, and will capture the visible part of the spectrum without too much voltage loss. The next cell is GaAs, which has a band gap of 1.42 eV, and will capture the red to infrared part of the spectrum. The bottom junction is formed in the Ge substrate, which has a band gap of 0.67 eV and will capture the light further into the infrared. The triple-junction cell, in production, can yield 27% (AM 0) conversion efficiency [46.7].

The layers of these multijunction cells are grown epitaxially onto a single-crystal Ge substrates. As with crystalline silicon, high crystalline quality is needed to obtain high-efficiency cells; polycrystalline GaAs does not work due to grain-boundary conduction that reduces the available photocurrent. This restricts the photovoltaic applications to high-quality epitaxial material and GaAs is not suitable for cheap thin-film photovoltaics on glass substrates. The topic of thin-film polycrystalline photovoltaics will be considered in the next section on CdTe solar cells. Epitaxial growth avoids minority-carrier recombination at grain boundaries, by avoiding their formation, but the cost of the substrates is inherently higher than the glass or ceramic substrates used for thin-film devices. However, defects must also

be avoided at the junction and interfaces between layers of different composition and this imposes the constraint that the heterostructures should be lattice matched. This restricts the choice of alloys to those that are either lattice matched or that the thickness and mismatch are such that the film is strained. The simplest structures use AlGaAs, which has a close lattice match to GaAs over the entire composition range, as a window and passivation layer. GaAs is also closely matched to Ge, offering a choice of substrates. The GaAs or Ge substrate is the narrowest-band-gap part of the structure, so the device has to be front-side illuminated with a grid of metal contacts on the top surface to contact the cells. The design of the cell structure needs to have the wider-band-gap layers further from the substrate (last to be grown) to allow the longer wavelengths to penetrate to the narrow-band-gap absorber layer. This places further constraints on the design of these epitaxial structures.

The Ge and GaAs substrates have a similar lattice parameter to AlGaAs, which is used as a passivation layer for both n-type and p-type GaAs layers. Other III–

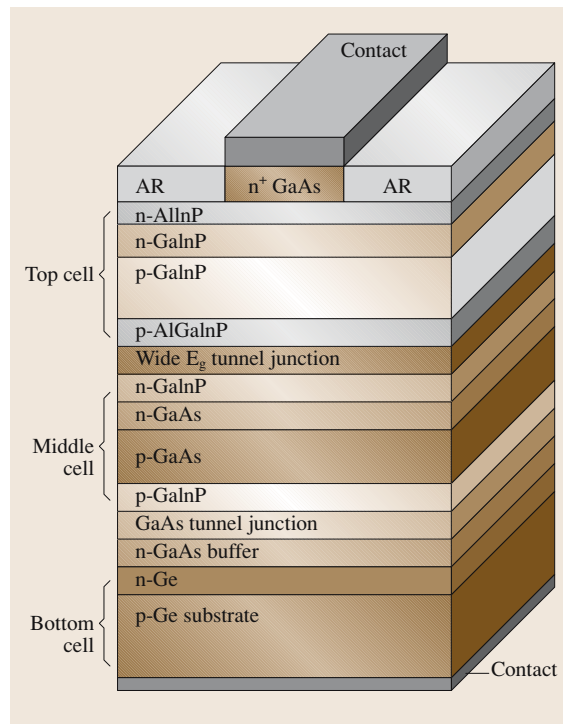

Fig. 46.7 Schematic of a triple-junction GaAs solar cell [46.7], showing the positions of the three junctions

V compounds that can be used include GaSb, which is sensitive to the near infrared out to $1.8\text{ }\mu\text{m}$ and will therefore absorb the radiation that is transmitted through the GaAs cell, as an alternative to the Ge-bottom cell. The alloy GaInP also lattice matches for the 50% Ga/In mix and is useful as a wider-band-gap junction. GaSb is also attractive for thermo-photovoltaics where the solar radiation is converted into heat, which is then absorbed by the narrow-band-gap GaSb device. More recently, the narrow-band-gap quaternary GaInNAs has been investigated [46.9] as a narrow-band-gap absorber layer and can be inserted between the GaAs layer and the Ge substrate to give a small boost in voltage.

The III–V photovoltaic structures are grown by metalorganic vapour-phase epitaxy (MOVPE), which gives excellent control over alloy composition and doping concentration. An example of a multijunction cell is shown

in Fig. 46.7. The structures tend to be complex because a tunnel junction is needed for current to flow between the two (series) photovoltaic cells, otherwise the connection between the two would be a high-impedance reverse-bias junction. It is also important for the device design to match the currents between the two (or more) junctions so that they can both operate at near-optimum conditions.

GaAs solar cells are rapidly increasing their share of the space market to power satellites. Their efficiency is high, stability good but the single-crystal substrates increase the cost. There may be toxicity issue for the disposal of solar modules if GaAs was used widely for terrestrial applications. The most attractive terrestrial application would be in concentrators where the solar radiation is optically concentrated onto the PV cells, so the collection area can be much greater than the area of expensive PV modules.

46.5 CdTe Thin-Film Solar Cells

The band gap of CdTe of 1.45 eV at room temperature makes it another semiconductor that is close to the theoretical optimum for efficient conversion of solar radiation (see Fig. 46.5) into electrical power. The absorption coefficient is $> 5 \times 10^4\text{ cm}^{-1}$ for photon energy greater than the band gap, allowing efficient collection for only $2\text{-}\mu\text{m}$ -thick films, similar to GaAs. CdTe, like GaAs is also a direct-band-gap semiconductor but is from the II–VI family of semiconductor compounds. Although the theoretical efficiency for the CdS/CdTe photovoltaic cell is $\approx 30\%$ at AM 1.5, the highest values reported are nearly half this maximum and are less than 10% at AM 1.5 for modules in production. The attraction of CdTe compared with GaAs is that these cells can be made from polycrystalline thin films on glass substrates, thus avoiding the need for expensive single-crystal substrates. A further advantage in using glass substrates is that illumination of the photovoltaic cell occurs through the substrate rather than from the top face, so the substrate becomes the window for the cell. The front contact is made with a transparent conducting oxide (TCO) such as ITO, as shown in Fig. 46.8, and this avoids the need for an opaque grid of metal contacts. This approach of using a TCO on glass substrate as the window is called a superstrate. The TCO has to have high optical transmission as well as a metal-like electrical conductivity. A typical spreading resistance would be $10\text{ }\Omega$ per square.

The CdTe solar cell is made from a heterojunction between the wider-band-gap CdS and the CdTe absorber layer. CdS is often referred to as the window layer; it has a band gap of 2.4 eV allowing most of the visible spectrum to pass with very little absorption. The

Fig. 46.8 Schematic of a CdTe device structure based on a glass superstrate

most common method for depositing CdS is by chemical bath deposition (CBD). The layer is n-type, forming a junction with the p-type CdTe. The thickness is kept to a minimum (around 100–200 nm) in order to minimise absorption at the blue end of the spectrum. A schematic of the CdTe PV structure is shown in Fig. 46.9.

Deposition techniques for CdTe (electrodeposition or close-space sublimation (CSS)) require post-deposition treatment for doping, grain growth and resistivity reduction, at temperatures above 400 °C. The exact processes are not clear but improve the efficiency from a few % to > 10% if this anneal is carried out in air in the presence of CdCl₂ [46.10]. There are variations in this process in terms of temperature, time and ambient gas but all involve the diffusion of Cl into the CdTe and some interdiffusion of the CdS/CdTe interface. This process improves grain size to $\approx 1\text{ }\mu\text{m}$ if the starting material has a much smaller grain size. This is further complicated by the variations in grain size from the CdS interface up to the back surface, where the junction region displays smaller grains. The best efficiency in the laboratory is 16.5% reported by Wu [46.11]. Production-scale processes achieve somewhat lower efficiencies, typically 8–10% [46.12].

A typical CdTe module with an area of 0.94 m² has a peak output power of 70 W; this compares favourably with other thin-film photovoltaics but is still much lower than the crystalline silicon modules [46.13]. However, the cost advantage and long-term stability make CdTe modules an attractive candidate for terrestrial applications. Future prospects for CdTe can be seen in current research activities with encouraging results for CdTe solar cells on flexible plastic substrates [46.14]. Using these substrates places tighter constraints on deposition and annealing temperatures and alternatives to the CdCl₂ anneal would be attractive. One prospect is for in situ doping of CdTe with arsenic to make it p-type using metalorganic chemical vapour deposition (MOCVD). This technique has been successfully used in the past to deposit films that were given a conventional anneal treatment. MOCVD offers greater flexibility over deposition conditions but would also need to compete with CSS and electrodeposition on cost of deposition.

Fig. 46.9 Schematic of CIGS device structure based on a glass substrate

The abundance figures look low but up to 5000 tons of Te could be produced each year from copper ore and 20 000 tons of Cd is produced each year as a by-product of zinc production. An important environmental and resource issue may be the recycling of these materials. It is important to note that although Cd is a very toxic metal it is relatively benign in the form of CdTe as it is a very stable compound and is not soluble in water. The use of Cd in solar cells has the added benefit of making use of the Cd that is produced as a by-product of zinc production in an environmentally friendly way. Jager-Waldau [46.6] states that “Every energy source or product may present some environmental, health and safety hazard, and those of CdTe should by no means be considered barriers to technology scaling”. This technology is less well developed than those in the other case studies but the thin-film technology on glass combined with good stability makes this a very attractive proposition for both terrestrial and space applications.

46.6 CuInGaSe₂ (CIGS) Thin-Film Solar Cells

This is an alternative material system for achieving an optimum band gap for solar energy conversion and one that has attracted a lot of research effort in the

past 10 years with impressive improvements in conversion efficiency. The highest efficiency reported for laboratory solar cells is 19.2%, which is currently the

best of the thin-film PV technologies [46.15]. In common with other thin-film PV technologies, these films can be deposited onto cheap substrates, at relatively low temperature, and the potential for processing in large volumes. The absorber layer is based on the Chalcopyrite-phase CuInSe_2 (CIS). This has a band gap of 1.04 eV, which is lower than the optimum band gap for optimum efficiency. However, cells made from CIS have achieved > 10% efficiency. Alloying with Ga to form $\text{CuIn}_{1-x}\text{Ga}_x\text{Se}_2$ (CIGS) increases the band gap to 1.7 eV for $x = 1$. This gives a range of alloy composition across the important, optimum, range for efficient conversion. An increase in band gap will increase the voltage of the cell (V_{oc}) but decrease the number of absorbed photons, thus decreasing J_{sc} . In practice the alloy is not uniform and thus a greater proportion of the photon flux is absorbed by the single-junction device than would occur for a single wide-band-gap absorber layer [46.16]. The other benefit of grading of the alloy composition is that the resultant band-gap grading creates a built-in electric field that can drift the electrons towards the junction.

Unlike a-Si and CdTe, the preferred arrangement is not to illuminate through the substrate but illuminate from the top surface as with the crystalline GaAs cells. The typical layer structure is shown in Fig. 46.9. The substrate is soda-lime glass with a sputtered coating of molybdenum which acts as the back contact. The next layer is the $\text{CuIn}_{1-x}\text{Ga}_x\text{Se}_2$ alloy, which is the p-type absorber layer. The junction is formed with a thin layer of CdS (as with CdTe). The front contact is formed by aluminium-doped ZnO, which is highly conducting but transparent, allowing solar radiation to pass without significant absorption. One disadvantage of the substrate approach is that the top surface is protected with another glass sheet when it is fabricated into a solar module. This step is not necessary in the superstrate approach. However, the substrate configuration has shown much higher maximum efficiencies than the superstrate approach and offers the opportunity to deposit the CIGS layers onto flexible metal foils. The structure for CIGS on metal foil substrates is similar to those on the Mo/glass substrates except for a barrier layer of SiO_2 between the metal foil and the Mo back contact. This is needed to reduce the diffusion of impurities into the active semiconductor

layer. However, one impurity, sodium, has to be put back in to give the desired doping properties for the CIGS absorber layer [46.17]. This impurity occurs naturally when cheap soda-lime substrates are used, as the sodium will diffuse from the glass substrate into the CIGS layer during film deposition and annealing. Using metal foil substrates makes the PV cells flexible and enables their manufacture in a continuous reel-to-reel process.

There are various deposition methods that can be used for the deposition of CIGS and this can lead to low-cost production routes. The early results were obtained by co-evaporation from separate elemental sources. More recently a range of techniques have been used from e-beam evaporation of the metal sources and subsequent selenisation and annealing to electrodeposition. The characteristic of these approaches is a separation of the deposition process and alloy formation, allowing cheap and potentially high-throughput techniques to be used. This also enables control of the alloy composition and stoichiometry that will affect the doping [46.18]. The subsequently deposited junction layer, CdS, can be deposited by either chemical bath deposition, sputtering or CVD. The transparent contact layer, ZnO, is typically deposited by sputtering. All these techniques can be operated on a large industrial scale and lend themselves to cheap production methodology.

CIGS solar cells have moved rapidly into production and a number of manufacturers are offering modules with efficiencies in excess of 10%. For example, Shell Solar produce CIGS panel with a peak output power of 40 W for a module area of 0.42 m^2 . The potential price reduction is similar to other thin-film technologies and with a potential for breaking the critical 1 \$/W barrier, along with a-Si and CdTe. The current production cost is three to four times this value.

As with CdTe solar cells, the abundance of the elements In and Se appears low, but for a thin-film photovoltaic, where each module only needs a few grams of material, the total amount needed is not huge. However, the current price of In is high as it is not readily produced as a by-product of other mining processes. The cell stability for terrestrial applications appears to be good and has potential for space applications but more needs to be understood about the effects of high-energy γ fluxes on long-term stability.

46.7 Conclusions

This chapter has introduced some basic concepts about photovoltaic solar cells and examples of some of the

more common materials being used for solar-cell production. The area of research is huge with a number

of specialist journals dedicated to solar energy and large international conferences held annually. The drive to find cheaper solutions to the conversion of solar energy has taken research down some interesting and unusual avenues. One of the more successful of the alternative approaches is the dye-sensitised cell, known as the Gratzel cell after its inventor *Michael Gratzel* [46.19]. This uses organic dyes to absorb the solar radiation and transfer electrons to a porous TiO_2 surface, which is effectively the junction. Other approaches have looked at conducting polymers and polymer blends to form photovoltaic junctions. These approaches could enable very cheap photovoltaic solar cells to become a reality but over a much longer timescale than for the materials considered in this chapter.

All the materials considered here are in production and look set to make a major contribution to the production of solar energy over the next 10 years. The largest and most mature production facilities are based on crystalline or multicrystalline silicon. These modules are also the most efficient for single-junction cells. The most efficient modules are made from GaAs on Ge and are the most complex and most expensive. Most of this production is for the space market but increasingly is showing potential for use with concentrators for terrestrial appli-

cations. This is acceptable for stand-alone solar power generation but the largest challenge for large-scale terrestrial power generation is to integrate photovoltaic modules into buildings. The equivalent of a gigawatt power station would require, at least, of the order of 10^7 m^2 of solar modules. In reality it would have to be much larger to account for the average power production being much less than the peak production. A modest installation would have approximately 100 m^2 of solar panels so we would need more than 10^5 buildings. So, the goal has to be that every house and building has a PV façade or roof.

Large-scale implementation will require the modules to be architecturally acceptable, in appearance and size, and probably serve multiple functions such as keeping the rain out and heat in etc. This need is opening the opportunity for a range of materials and designs and ultimately flexible panels. On top of this the cost per watt of electricity produced needs to come down, probably by a factor of five based on current installed costs. The thin-film technologies are inherently cheaper but much of this cost benefit is not realised at present because the efficiencies and production volumes are low. The current growth in PV solar energy after decades of research has become very rapid and this expansion is set to continue well into the future.

47. Silicon on Mechanically Flexible Substrates for Large-Area Electronics

Low-temperature thin-film semiconductors and dielectrics are critical requirements for large-area electronics, including displays and imagers. Despite the presence of structural disorder, these materials show promising electronic transport properties that are vital for devices such as thin-film transistors (TFTs). This chapter presents an overview of material and transport properties pertinent to large-area electronics on mechanically flexible substrates. We begin with a summary of process challenges for low-temperature fabrication of a-Si:H TFTs on plastic substrates, followed by a description of transport properties of amorphous semiconducting films, along with their influence on TFT characteristics. The TFTs must maintain electrical integrity under mechanical stress, induced by bending of the

flexible substrates. Bending-induced changes are not limited to alteration of device dimensions and involve modulation of electronic transport of the active semiconducting layer.

There is growing interest in low-temperature thin-film semiconductors and dielectrics for a variety of applications such as organic light-emitting diode (OLED) displays and lighting modules [47.1, 2], solar cells [47.3], and digital imagers [47.4, 5]. Interest in these materials is driven by the promise of low-cost roll-to-roll manufacturing [47.6]. They enable high-performance electronic devices including thin-film transistors (TFTs), OLEDs, and p-i-n photodetectors on large-area mechanically flexible plastic substrates. OLEDs are becoming increasingly attractive as emission devices due to their fast response, high conversion efficiency, wide viewing angle, and compatibility with plastic substrates [47.7]. In high-information-content displays, the OLED must be integrated with a TFT circuit that provides stable drive currents [47.8]. Here, low-temperature a-Si:H TFTs or (solution-processed/vacuum-deposited) organic TFTs can be used to realize these circuits.

In addition to advances in material deposition and integration technologies, significant research efforts are being undertaken to improve the lifetime of the TFT and the OLED in view of instabilities induced by bias stress and exposure to ambient con-

ditions. The instability of TFTs stems from structural and interfacial disorder in the semiconductor and insulator layers, and interfaces. This leads to a shift in the threshold voltage ΔV_T under prolonged bias stress in a-Si:H [47.9] and organic [47.10] TFTs. To deal with the shift in device parameters, pixel circuits and driving schemes that can provide compensation have been proposed and are well under investigation [47.11]. The lifetime of the OLED, on the other hand, can be enhanced by efficient thin-film encapsulation layers with water-vapor permeation rates $< 10^{-6}$ g/m²/day at 25 °C and less than 40% relative humidity [47.12], which are imperative for active matrix organic light-emitting diode (AMOLED) displays on plastic substrates.

This chapter presents an overview of material and transport properties pertinent to mechanically flexible amorphous-silicon electronics. We begin with an overview of low-temperature fabrication of high-performance a-Si:H transistors and associated processing challenges. The transport properties of amorphous semiconducting films are then presented, along with their influence on TFT characteristics. We also examine the impact of external mechanical stress,

induced by bending of the flexible substrate, on the characteristics of thin-film devices, including strain gauges and TFTs. The shifts are not only limited to

changes in device dimensions but also to a modulation of electronic transport of the active semiconducting layer.

47.1 a-Si:H TFTs on Flexible Substrates

Compared to conventional (rigid) glass substrates, mechanically flexible substrates are attractive because of their reduced fragility and weight [47.13]. Polyethylene terephthalate (PET) [47.14] and polyimide [47.15] are examples of such substrates. Most plastic substrates have a low glass-transition temperature T_g ($< 250^\circ\text{C}$). Consequently, the device processing temperatures must be reduced without compromising the electronic properties of the deposited materials. Despite the adverse effects of reducing the processing temperature, high-performance low-temperature ($< 150^\circ\text{C}$) processes have been developed for fabrication of a-Si:H TFTs on flexible substrates [47.14–16], and even lower temperature processes (75°C) are under investigation [47.17].

One of the key challenges in low-temperature fabrication is to achieve a high-quality a-SiO_x [47.17] or a-SiN_x:H [47.16] gate and/or passivation dielectric with low defect density, leakage, and interface state density. Nitrogen rich ($x = 1.6$ to 1.7) a-SiN_x:H films with high resistivity ($\rho > 10^{15} \Omega\text{-cm}$) and breakdown field ($> 5 \text{ MV/cm}$) have been deposited using conventional 13.56 MHz plasma-enhanced chemical vapor deposition (PECVD) at 120°C [47.16].

The fabrication challenges are not limited to the electrical quality of the deposited materials. Most plastic substrates have a large coefficient of thermal expansion (CTE) ($> 50 \text{ ppm}/^\circ\text{C}$), which is much higher than that of the TFT layers ($\approx 4 \text{ ppm}/^\circ\text{C}$) [47.18]. As the deposited films go through a temperature drop ΔT upon cooling from the process temperature [47.2], thermal

stress $\sigma_{\text{th}} = Y_f \Delta C \Delta T$ develops in the film [47.19]. Here, ΔC is the difference between CTEs of the substrate and the film, and Y_f denotes the biaxial elastic modulus of the deposited film. The thermal stress bends the composite structure, giving rise to handling problems. Thus, the substrate needs to be held flat in a frame or glued to a rigid substrate [47.2]. In addition, since most layers are patterned during processing, the thermal stress exhibits a local pattern-dependent distribution, which leads to problems in alignment of consecutive masks. Lowering the process temperature and choosing a substrate with a smaller CTE, e.g. polyethylene naphthalate (PEN) with a CTE of $13 \text{ ppm}/^\circ\text{C}$ [47.18], will help alleviate the thermal stress, and associated alignment issues. It is important to note that thin rigid (steel, aluminum, or glass) substrates are also mechanically flexible and are being considered for device fabrication [47.20]. Although these substrates can withstand higher temperatures, handling issues still remain and depend on the desired degree of mechanical flexibility.

Recent work on TFT fabrication on flexible substrates is starting to demonstrate successful handling of material processing issues. For instance, TFTs fabricated on plastic substrate at 150°C have been reported to have parameter values very similar to the high-temperature counterparts in terms of low reverse and high on current (with switching ratio of $> 10^8$), high field-effect mobility $> 0.8 \text{ cm}^2/\text{Vs}$, threshold voltage of $\approx 1\text{--}2 \text{ V}$, and low subthreshold slope $< 0.3 \text{ V/dec}$ [47.16].

47.2 Field-Effect Transport in Amorphous Films

The electronic properties of a semiconducting film are primarily determined by its structural disorder and grain size, which strongly depend on deposition conditions and postprocessing treatment [47.21].

The structure of disordered semiconductors such as a-Si:H lacks the long-range periodicity of crystalline silicon. However, the atoms of the materials bond to their neighbors according to the 8-N rule [47.22]

for both amorphous and crystalline silicon, leading to short-range structural order. The extent to which this short-range order is conserved is dependent on processing conditions and leads to different degrees of disorder. This range can be as small as a few nanometers in amorphous semiconductors or as large as a few tens of microns in polycrystalline material. Nanocrystalline (nc) and microcrystalline (μc) materials reside

between these extremes depending on grain size and stoichiometry.

The observation of an absorption gap and thermally activated conductivity in amorphous semiconductors stems from the short-range order [47.24] and resembles the band-gap properties of an ideal crystalline semiconductor, which has no states in the gap. The edges of the gap are well defined and represent discontinuities in the density of states (DOS). In contrast, the lack of long-range order in the amorphous semiconductor leads to the presence of states in the gap, and thus, tailing of the band edges.

47.2.1 Localized and Extended States

In the ideal crystalline semiconductor, the band states are all extended with a corresponding band mobility μ_{band} . In the case of an amorphous semiconductor, however, the structural disorder of the material leads to the presence of localized states for which the mobil-

ity vanishes at $T = 0$. Anderson [47.25] demonstrated that, for a sufficiently large degree of disorder, all states in the band are localized. In his work, the disorder in the material is modeled by a random but uniform distribution U_0 for the energy of the wells at lattice sites. He found that all of the states of the energy band become localized when $U_0/B > 5$, where B is the band width and is given by $B = 2ZI$ [47.22]. Here, Z is the coordination number, and I the overlap energy for the states in neighboring wells, which decreases exponentially with distance based on the tight-binding approximation.

For a small degree of disorder, Anderson's criteria may not hold for states with large overlap energies (i. e. the extended states). Mott and Davis [47.22] have stipulated that, for a given value of U_0 , the states can be localized or extended, depending on their overlap energy. Consequently, for some materials there are distinct energies which separate the localized states from the extended ones and can be determined from Anderson's criteria $U_0 \approx 5B$. These energies are referred to as mobility edges (or mobility shoulders) due to the significant change in the mobility expected at these edges. Figure 47.1 illustrates the DOS $g(E)$ for the mobility gap of a-Si:H indicating the extended and localized states. The mobility shoulder E_C of the conduction band separates the localized states from the extended ones. A similar band structure and mobility shoulder is present for the valence band. This graph is compiled from the work of Cohen et al. [47.23], who first demonstrated that the change in mobility at these edges can be of the order of 10^3 – 10^4 , signifying the different transport mechanisms on the two sides of the edge.

In the extended states, the carriers have a finite mobility, and thus take part in metallic-type conduction. This prevails at room temperature for a-Si:H and takes the form $\sigma_0 = 0.06q^2/\hbar r(E)$ [47.22], where q is the elementary charge and $r(E)$ the mean distance between the wells that contribute to states with energy E . In the conduction band, $r(E)$ will be close to the lattice constant, which yields $\sigma_0 = 350 \Omega^{-1} \text{cm}^{-1}$. For Fermi energies $E_F < E_C$, the conductivity depends on the Fermi energy and reads

$$\sigma = \sigma_0 \exp(E_F/k_B T), \quad (47.1)$$

where k_B is Boltzmann's constant and T the temperature, predicting Arrhenius behavior for the conductivity. Here, E_F is defined as negative for the traps with respect to the conduction band edge E_C . This change in conductivity is due to a change in the concentration of carriers, excited to the extended states n_{band} with a band mobility

Fig. 47.1a,b Sketch of (a) DOS in valence and conduction bands, and (b) hole and electron mobilities (after [47.23])

μ_{band} such that

$$\sigma = q\mu_{\text{band}}n_{\text{band}}, \quad (47.2)$$

where

$$n_{\text{band}} = N_b \exp(E_F/k_B T), \quad (47.3)$$

with $N_b = \sigma_0/q\mu_{\text{band}}$. From the given value for σ_0 , the band mobility can be found as $\mu_{\text{band}} \approx 12 \text{ cm}^2/\text{Vs}$ for a-Si:H.

In the localized states, the conduction is only possible by hopping of the carriers to the neighboring localized states [47.26]. This method of conduction prevails at low temperatures ($T < 200 \text{ K}$) and for highly disordered materials.

The picture of the mobility gap can be completed by adding defect states in the middle of the gap, as indicated by the dashed lines in Fig. 47.1a. These states are attributed to the broken or unsaturated bonds such as dangling bonds in the network structure. The density of dangling bonds is reduced to $10^{15} - 10^{16} \text{ cm}^{-3}$ in a-Si:H by hydrogen atoms, which passivate some of these unsaturated bonds [47.24, 27].

47.2.2 Density of States (DOS)

The density of states (DOS) $g(E)$, including the density of band tail and defect states, as schematically represented in Fig. 47.1a, determines the transport properties of the disordered semiconductor. The DOS in

a-Si:H has been extensively studied by using different experimental techniques such as field-effect measurements [47.28, 29], photoconductivity measurements [47.30], deep-level transient capacitance spectroscopy (DLTS) [47.31], and capacitance–voltage–frequency ($C-V-f$) characteristics [47.32, 33]. It is found that an exponential distribution of the deep and tail states [47.34] can efficiently describe the distribution of the localized states and hold for a wide range of materials with rapidly changing DOS. In the case of a-Si:H, the localized states in the upper half of the mobility gap, closer to E_C , behave as acceptor-like states, while the states in the lower part of the gap, closer to E_V , behave as donor-like states. Acceptor-like states are neutral when they are empty, and negatively charged after capturing an electron, whereas the donor-like states are positively charged when they are empty and neutral after capturing an electron.

In a-Si:H, the number of donor-like states closer to the valence band is much higher than the number of acceptor-like states. As a result, following the neutrality condition, the position of the Fermi energy E_i in an intrinsic a-Si:H sample in the dark lies closer to E_C due to the asymmetrical DOS distribution [47.27]. This results in a much stronger electron conduction in a-Si:H, which signifies the role of the conduction band tail in dispersive electron transport. The density of states for the conduction band tail $g(E)$ is written as

$$g(E) = N_t/k_B T_t \exp(E/k_B T_t), \quad (47.4)$$

where N_t is the total acceptor-like states in the conduction band tail, and T_t the associated slope of the exponential state distribution.

47.2.3 Effective Carrier Mobility

Due to the high density of tail and deep states, only a small number of carriers are thermally excited to the extended states and contribute to conduction as described in (47.2). The total carrier density n is the sum of the excited and trapped carriers such that

$$n = n_{\text{band}} + n_t. \quad (47.5)$$

To obtain the trapped carrier density n_t as a function of the Fermi energy E_F , we integrate the product of the DOS and the probability of occupation of a state $f(E)$ over the mobility gap

$$n_t = \int_{E_V}^0 g(E)f(E)dE. \quad (47.6)$$

Fig. 47.2 Density of trapped carriers as a function of the Fermi energy, showing the reference concentration N_0 and transport (conduction) band

In equilibrium, the probability of occupation can be described by the Fermi–Dirac function,

$$f(E) = \frac{1}{1 + \exp[(E - E_F)/k_B T]} . \quad (47.7)$$

Equation (47.6) can be numerically solved and approximated along the lines given by *Shaw and Hack* [47.37] as

$$n_t(E_F) = N_t \exp(E_F/k_B T_i) u(T_i/T, E_F) . \quad (47.8)$$

The underlying assumption is that E_F moves no closer than a few $k_B T$ to the mobility edge. This is true because of the high density of tail states, which tends to pin the movement of the Fermi energy. Here, $u(T_i/T, E_F)$ represents the changes in the trapped-carrier density with normalized ambient temperature T_i/T . For $T \ll T_i$, $u(T_i/T, E_F)$ is often approximated by $[\sin(\pi T/T_i)/\pi T/T_i]$ [47.38] with a value close to 1. The ratio T_i/T , referred to as the dispersion parameter, characterizes the dispersive transport of electrons in the conduction band tail, and can be obtained from the time dependence of the electron drift mobility in time-of-flight experiments [47.39]. The presence of a high trapped-carrier density in amorphous semiconductors leads to an effective trapped-carrier mobility that is lower than the band mobility. *Street* [47.27] has defined the drift mobility μ_D of the carriers as the band mobility reduced by the fraction of time that the carrier is trapped,

$$\mu_D = \mu_{\text{band}} \frac{\tau_{\text{band}}}{\tau_{\text{band}} + \tau_{\text{trap}}} , \quad (47.9)$$

where τ_{band} and τ_{trap} are the times that carriers spend in the extended and localized states, respectively.

Carriers accumulated by the field effect in TFTs also demonstrate similar transport properties. The field-effect mobility μ_{FE} in TFTs is conventionally defined as

$$\mu_{\text{FE}} = g/qn , \quad (47.10)$$

where g is the conductance of the film, and qn is the field-induced charge in the semiconducting film. The terms g and n are averaged over the device active area and are related to the number of band carriers n_{band} and trapped carriers n_t . The μ_{FE} is conventionally retrieved from measurement of the transistor current ($I_{\text{DS,lin}}$) in the linear regime ($V_{\text{DS}} = 0.1$ V), by using the following:

$$\mu_{\text{FE}} = \frac{L}{WC_i V_{\text{DS}}} \frac{\partial I_{\text{DS,lin}}}{\partial V_{\text{GS}}} , \quad (47.11)$$

where W and L are the channel width and length, respectively, C_i the gate capacitance, and V_{GS} and V_{DS} are the gate–source and drain–source biases, respectively.

According to (47.3) and (47.8), the densities of the band and trapped carriers increase differently with increasing E_F . Consequently, when n_{band} and n_t are averaged over the volume of the semiconducting film to obtain the μ_{FE} described by (47.10), the mobility becomes a function of device parameters (e.g. layer thicknesses and bias conditions).

The bias dependence is also evident in temperature-dependence measurements of mobility and conductivity in a-Si:H and organic TFTs. Figure 47.3 illustrates the temperature dependence of μ_{FE} for a-Si:H, pentacene and polythienylene vinylene (PTV) [47.36], and poly[5,5'-bis(3-alkyl-2-thienyl)-2,2'-bithiophene] (PQT-12) [47.35,40] TFTs at different gate biases. Here, the activation energy E_a turns out to be bias-dependent (inset of Fig. 47.3). More importantly, an anomaly arises in which the μ_{FE} and E_a become dependent on the gate capacitance C_i , which is solely a geometrical capaci-

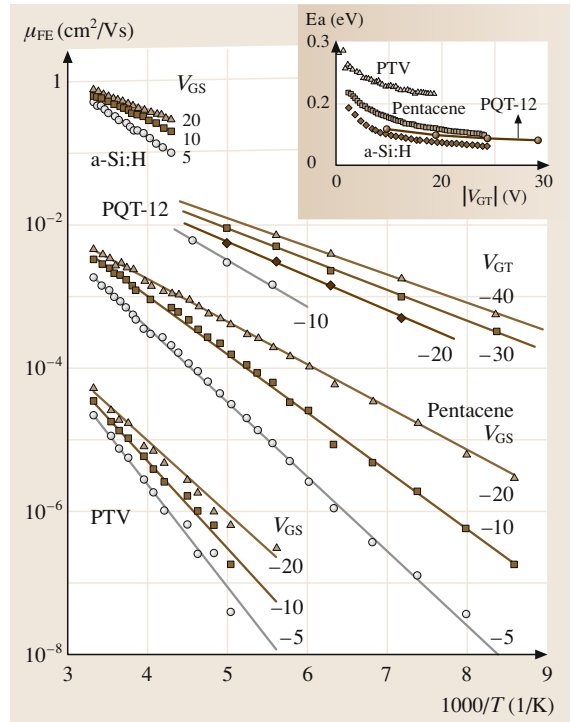

Fig. 47.3 Temperature dependence of μ_{FE} for a-Si:H, PQT-12 [47.35], pentacene and PTV [47.36]. Inset shows the bias dependence of the activation energy E_a of μ_{FE} in these materials

tance. A higher C_i implies higher carrier accumulation and consequently higher μ_{FE} for the same bias.

To remove this anomaly, we need to identify the effective carrier mobility such that $\mu_{FE} = \mu_{eff} \times f(\phi)$, where μ_{eff} is the effective physical mobility and $f(\phi)$ describes the device attributes such as bias and geometry.

We reconsider the densities of trapped and free carriers according to (47.3) and (47.8). Since both densities vary exponentially with the Fermi energy, the density of band carriers in terms of trapped carriers can be written as

$$n_{band} = \theta n_t^{T_i/T}, \quad (47.12)$$

where $\theta = N_b/(N_t u)^{T_i/T}$. Equation (47.12) has been found to hold empirically for a wide range of disordered semiconductor systems and operating conditions, including organic semiconductors [47.41, 42].

According to (47.2) and (47.12), the conductivity $\sigma(n)$ as a function of carrier concentration can be written as

$$\sigma(n) = q\mu_{eff} N_0 (n/N_0)^{T_i/T}, \quad (47.13)$$

where μ_{eff} is the effective mobility defined at a reference concentration as

$$\mu_{eff} \equiv \frac{\sigma(n = N_0)}{qN_0} = \mu_{band} \frac{N_b}{N_0} \left(\frac{N_0}{N_t u} \right)^{T_i/T}. \quad (47.14)$$

Consequently, the conductivity at any carrier concentration is given by μ_{eff} and T_i/T . Here, μ_{eff} represents the effective carrier mobility at concentration N_0 and T_i/T describes the change in conductivity with carrier concentration.

The significance of this representation becomes clear when we use it to obtain the current–voltage characteristics of a TFT (Fig. 47.4). Using the gradual channel

Fig. 47.4 Simplified schematic of an inverted staggered TFT

approximation, we can write

$$I_{DS,lin} = \frac{W}{L} V_{DS} \int_0^\delta \sigma(y) dy, \quad (47.15)$$

where y denotes the location across the channel and δ the channel depth. Using (47.13) for σ and changing the integral parameter from y to n , we find after mathematical manipulation [47.43]

$$I_{DS,lin} = \mu_{eff} \zeta \frac{W}{L} (C_i V_{GT})^{\alpha-1} V_{DS}, \quad (47.16)$$

where $V_{GT} = V_{GS} - V_{thr}$, V_{thr} the threshold voltage, $\alpha = 2T_i/T$ the saturation current–voltage characteristics power parameter, and

$$\zeta = \frac{(2\epsilon k_B T_i N_0)^{1-\alpha/2}}{\alpha - 1}. \quad (47.17)$$

Here, ζ is just a function of T_i/T and accounts for the carrier distribution across the film. Revisiting the definition of the field-effect mobility as given by (47.11), but this time employing a more meaningful representation of the current, i. e. (47.16), we find

$$f(\phi) \equiv \frac{\mu_{FE}}{\mu_{eff}} = \zeta (\alpha - 1) (C_i V_{GT})^{\alpha-2}. \quad (47.18)$$

Representation of μ_{eff} according to (47.14) is valid only when there is an exponential relationship between the carrier concentration n and the Fermi energy E_F as given by (47.8). This is true for Fermi energy locations below the transport band edge and above the energies of the deep states (the region shown by the solid slope in Fig. 47.2). Since the deep states mostly contribute to the threshold voltage V_{thr} and are filled before the device turns on, the mobility definition of (47.14) is valid for the above-threshold regime. Consequently, the value of the reference concentration N_0 must be selected such that the Fermi energy E_{F0} associated with N_0 resides well above the deep states. This requires the charge accumulated in the channel $Q_{channel}$ to be higher than the charge $C_i V_{thr}$ needed to turn on the device. If the carrier concentration at the semiconductor interface is N_0 , $Q_{channel} = C_i V_0$, where $V_0 = (2\epsilon k_B T_i N_0)^{1/2}/C_i$. Thus, for $Q_{channel} > C_i V_{thr}$, we conclude $V_0 > V_{thr}$ or $N_0 > C_i^2 V_{thr}^2 / (2\epsilon k_B T_i)$, indicating the lower limit for N_0 . Using typical values, $V_{thr} = 2$ V and $C_i = 20$ nF/cm², we have $N_0 > 6 \times 10^{16}$ cm⁻³. For instance, with $N_0 = 10^{17}$ cm⁻³, we have for the bias dependence factor $\zeta = (4.1 \times 10^{-16} \alpha)^{(1-\alpha/2)} / (\alpha - 1)$.

We now revisit the temperature dependence of μ_{eff} by recasting (47.14) in the following manner

$$\mu_{eff} = \mu_{eff0} \exp(-E_{a0}/k_B T), \quad (47.19)$$

Table 47.1 Extracted transport parameters (μ_{eff} , T_i , and E_{a0}) for a selection of disordered semiconductors at $N_0 = 10^{17} \text{ cm}^{-3}$

Semiconductor	μ_{eff} at 300 K (cm^2/Vs)	T_i (K)	E_{a0} (eV)	Reference
a-Si:H	0.98	350	0.23	Our measurements
PQT-12	3.9×10^{-2}	326	0.24	[47.35]
Pentacene	9.0×10^{-4}	385	0.31	[47.36]
PTV	1.1×10^{-5}	380	0.42	[47.36]

where

$$\mu_{\text{eff}0} \equiv \mu_{\text{band}} \frac{N_b}{N_0} \quad \text{and} \quad E_{a0} \equiv k_B T_i \ln \left(\frac{N_i \mu}{N_0} \right) = -E_{F0}. \quad (47.20)$$

Equation (47.19) predicts Arrhenius behavior for the effective mobility with an activation energy of $E_{a0} = -E_{F0}$ (Fig. 47.2). The activation energy of μ_{eff} is not bias-dependent and corresponds to the energy needed for carriers to thermalize from E_{F0} to the mobility edge.

We now examine the relation between the two activation energies E_a and E_{a0} . To do so, we look at the temperature dependence of μ_{FE} and μ_{eff} , viz.,

$$\begin{aligned} \frac{\partial \mu_{\text{FE}}}{\mu_{\text{FE}} \partial T} &= \frac{\partial \mu_{\text{eff}}}{\mu_{\text{eff}} \partial T} + \frac{\partial f(\phi)}{f(\phi) \partial T} \\ &= -\frac{E_{a0}}{k_B T^2} + \frac{2T_i}{T^2} \ln \left| \frac{V_{\text{GT}}}{V_0} \right|, \end{aligned} \quad (47.21)$$

which yields

$$E_a = E_{a0} - 2k_B T_i \ln |V_{\text{GT}}/V_0|. \quad (47.22)$$

Equation (47.22) describes the bias dependence observed for E_a in the inset of Fig. 47.3.

Amorphous Organic Semiconductors

The concept of effective mobility and transport band may be generalized to accommodate different amorphous organic semiconductors despite differences in the underlying transport mechanism. This generalization follows from the relation $n_{\text{band}} = \theta n^{T_i/T}$ (47.12) for organic semiconductors for a wide range of temperatures and carrier concentrations [47.41]. For this relation

to hold, the distribution of trapped and band carriers must be exponential. Although evidence of a Gaussian trap distribution has been reported for organic materials [47.44], the Gaussian distribution is effectively seen as an equivalent exponential distribution due to the small variation in the Fermi energy because of the large tail state distribution. In addition, *Shapiro and Adler* [47.45] have demonstrated that a transport band is present in which hopping conduction dominates irrespective of the position of Fermi energy. Similar to the mobility edge, the trapped carriers are thermalized to the hopping band [47.26]. Relative to E_{F0} , the hopping band is located at

$$E_{0\text{hopping}} = k_B T_i \ln \left[\frac{\gamma^3}{N_0} \left(\frac{2T}{3T_i} \right)^3 \right], \quad (47.23)$$

where γ is the effective overlap parameter for electronic states in the band tail. *Baranovskii et al.* [47.46] have generalized this concept of transport band beyond the exponential DOS assumption and to a broader range of disordered materials with Gaussian or similar rapidly changing distributions. The generalized band concept can also accommodate the percolation-based hopping transport described by *Matters* [47.36] for amorphous organic semiconductors, which predicts a hopping band that is just $k_B T_i \ln (B_C/3\pi^3)$ higher than that predicted by *Monroe* [47.26]. Here, $B_C \approx 2.8$ is the critical number for percolation in three-dimensional amorphous systems. Table 47.1 summarizes the values for μ_{eff} at room temperature T_i , and E_{a0} at $N_0 = 10^{17} \text{ cm}^{-3}$, determined from the results presented for different disordered materials reported in literature.

47.3 Electronic Transport Under Mechanical Stress

Mechanical stress deforms the structure of the thin film leading to modulation in carrier mobility and density of states, and consequently, modulation of resistance.

The change in resistance of a solid with elastic strain or stress is commonly referred to as the *elastoresistance* or *piezoresistance* effect, respectively [47.47]. The

magnitude of the change is a function of the electronic properties of the material, the dimensions of the solid, and the direction of current flow.

Structural order in the material influences the elastoresistance effect. In the case of crystalline silicon, anisotropic scattering of electrons in the n-type material leads to a strong orientation dependence of the elastoresistive behavior [47.48]. In polycrystalline silicon, the crystallite size and orientation, and material texture play a critical role in determining the magnitude of the effect [47.49, 50]. In amorphous semiconductors, the random network behaves like an isotropic medium, and the anisotropy found in the crystalline material is less visible. However, the elastoresistance coefficients still depend on the relative orientation of the current and applied strain [47.51].

In sputtered amorphous silicon, *Welber and Brodsky* [47.52] have reported a decrease in the absorption gap with hydrostatic pressure with a coefficient of about -1 meV/kbar (-10^{-11} eV/Pa) observed from the shift in the absorption edge. *Weinstein* [47.53] has also reported similar results drawn from photoluminescence experiments. The change in the optical gap is similar in sign and magnitude to that measured for crystalline silicon [47.54]. *Lazarus* [47.55], however, has reported an exponential increase in the resistivity of a-Si:H with increasing hydrostatic pressure at room temperature. The increase in resistivity is ascribed to either a decrease in the number of carriers or a reduction of the mobility with compressive strain [47.51].

In this section, we investigate the impact of mechanical stress on electrical properties of thin-film devices, insight into which is critical for design of mechanically flexible electronics. We begin with metallic and semiconductor thin films for strain-gauge applications and continue with a-Si:H TFTs.

47.3.1 Thin-Film Strain Gauges

Strain gauges are thin-film transducer elements embedded on a substrate Fig. 47.5. The strain in the substrate leads to a change in the geometry, and therefore, the resistance of the gauge, which is detected and measured by external circuitry. The sensitivity of the resistance R to strain ϵ is referred to as the gauge factor k , which can be written as

$$k \equiv \frac{\Delta R}{\epsilon R} = \frac{\Delta L}{\epsilon L} - \frac{\Delta W}{\epsilon W} - \frac{\Delta t}{\epsilon t} + \frac{\Delta \rho}{\epsilon \rho}, \quad (47.24)$$

where ρ is the resistivity of the material, and W , L , and t are the width, length, and thickness of the strain

Fig. 47.5 Schematic of a thin-film strain gauge

gauge, respectively. The last term on the right-hand side of (47.24) reflects the strain-induced change in resistivity of the sample, whereas the first three terms refer to geometrical changes only.

Usually, the gauge length is oriented in a direction where strain is largest to achieve the highest gauge factor. This is referred to as the longitudinal orientation, where the current flows parallel to the strain. Similarly, the transverse orientation is defined when the gauge length is oriented in a direction perpendicular to the maximum strain (Fig. 47.6). The modulation of resistivity in the different orientations with the strain and correspondingly stress can be summarized by the following expression:

$$\frac{\Delta \rho_i}{\rho} = \gamma_{ij} \epsilon_j = \pi_{ij} \tau_j \quad \text{with } i = 1, 2, 3 \quad \text{and } j = 1, 2, \dots, 6, \quad (47.25)$$

where γ_{ij} and π_{ij} are the elements of the compact matrix of the elastoresistance and piezoresistance coefficients,

Fig. 47.6 Longitudinal and transverse wires under uniaxial stress and strain components in the 1-direction

respectively, and ϵ_j and τ_j denote the strain and stress components, respectively. (Here, we have used compact notation for these tensors [47.47].)

In metal gauges, the sensitivity of ρ to strain is assumed to be negligible, leading to the well-known longitudinal gauge factor of $k_l = 1 - 2\nu$, where ν is the Poisson's ratio. However, *Arlt* [47.56] has shown that the term $\Delta\rho/\rho$ also includes geometrical attributes. This is due to the change in the volume of the wire and the resulting change in carrier density. According to *Arlt* [47.56], we have for the longitudinal gauge factor

$$k_l = 2 - \frac{\Delta(\gamma\mu)_l}{\epsilon\gamma\mu}, \quad (47.26)$$

where γ denotes the number of free electrons per atom and μ the electron mobility. Since the last term on the right-hand side of (47.26) is relatively small for metallic gauges, the gauge factor mainly stems from geometrical changes; it is close to 2 and temperature independent [47.57].

These results can be validated using beam-deflection (cantilever) experiments performed on strain gauges integrated on glass and silicon substrates. Figure 47.7 illustrates the schematic of a beam-deflection system. One end of the sample is clamped ($x = 0$) and the free end is deflected by a displacement Δ . *Rajanna and Mohan* [47.58] used this method in measurements of both tensile and compressive configurations by simply placing the sample with the films on the top or bottom, respectively (see Fig. 47.7). The strain at location x along a sample with a length L_0 reads

$$\epsilon(x) = \pm \frac{3t_s\Delta}{2L_0^2}(1 - x/L_0), \quad (47.27)$$

with the positive and negative signs denoting tensile and compressive configurations, respectively.

Fig. 47.7 Schematic of a beam-deflection experiment

Fig. 47.8 Normalized change in output voltage of a longitudinal Mo strain gauge

Figure 47.8 illustrates the result of the beam-deflection experiment on a 150-nm-thick molybdenum strain gauge with 30 turns, line width of 20 μm , and length of 1100 μm . The strain gauges are biased with a constant current of 100 μA and the voltage drop across its terminals is measured. The gauges are subjected to a sequence of loading/unloading steps in tensile configuration to eliminate systematic errors associated with slowly varying transients. By averaging the value of the voltage modulation, we retrieve a gauge factor of approximately $k_l \approx 2.06$ for the longitudinal strain gauges.

The gauge factor for semiconductors is much higher due to the higher elastoresistance coefficients. *Dössel* [47.57] has related the gauge factor to the elastoresistance coefficients as follows:

$$k_l = \gamma_1 - (\nu_s + \nu_h)\gamma_2 \text{ and } k_t = -\nu_s\gamma_1 + (1 - \nu_h)\gamma_2,$$

where

$$\nu_h = \nu_f \frac{1 - \nu_s}{1 - \nu_f}, \quad (47.28)$$

and $\gamma_1 = 2 - \Delta(\gamma\mu)_l/\gamma\mu\epsilon$ and $\gamma_2 = \Delta(\gamma\mu)_t/\gamma\mu\epsilon$ are the elastoresistance coefficients, and ν_s and ν_f denote the Poisson's ratios for the substrate and the film, respectively.

The same beam-deflection experiment can also be performed on n^+ $\mu\text{c-Si:H}$ strain gauges. Figure 47.9 displays the results of tensile and compressive tests on metal and semiconductor gauges, indicating a higher gauge factor. The values are $k_l = -17.0$ and $k_t = -3.41$

Fig. 47.9 Change in voltage of longitudinal and transverse n^+ $\mu\text{c-Si:H}$ and longitudinal Mo gauges under tensile and compressive strains

for longitudinal and transverse semiconductor gauges, respectively. Assuming $\nu_s = \nu_f = 0.23$, we find that $\gamma_1 = -22$ and $\gamma_2 = -10.9$ for n^+ $\mu\text{c-Si:H}$ films.

The longitudinal gauge factor obtained for the n^+ $\mu\text{c-Si:H}$ gauges corroborate the results of Germer [47.59] for phosphorus-doped microcrystalline thin-film samples with a doping density of $\approx 10^{20} \text{ cm}^{-3}$. For the transverse gauge factor, Germer has observed a small (negative or positive) gauge factor for doping densities in the range $5 \times 10^{19} - 10^{20}$. This shows that the

Fig. 47.10 Change in TFT current in deflection experiments

Fig. 47.11 Normalized change in TFT current as a function of tensile and compressive strain

transverse gauge factor is highly sensitive to the doping density and other process conditions, which explains the slight difference between our values and that reported by Germer.

47.3.2 Strained Amorphous-Silicon Transistors

Figure 47.10 illustrates measurement results for the transient drain current of a longitudinal TFT subject to a sequence of tensile loading/unloading steps. We see immediate changes in current superimposed on the intrinsic transient response of the TFT. The measured change in current ΔI_D decreases with decreasing displacement. Correspondingly, we define the sensitivity

$$S_{\epsilon}(I_D) = \frac{1}{I_D} \frac{\partial \Delta I_D}{\partial \epsilon} \Big|_{\epsilon=\epsilon_0}, \quad (47.29)$$

Fig. 47.12 Longitudinal, transverse, and shear TFTs

Fig. 47.13 Bias dependence of the TFT current sensitivity

where I_D is the unstrained value of current and ϵ_0 a reference strain value.

Figure 47.11 depicts measurement results for the change in drain current of the longitudinal, shear, and transverse TFTs (Fig. 47.12) under tensile and compressive strains. The TFTs have $W/L = 400 \mu\text{m}/400 \mu\text{m}$ and are biased in the linear regime with constant $V_{GS} = 20 \text{ V}$ and $V_{DS} = 0.5 \text{ V}$. As seen in the figure, the results for compressive and tensile strain are similar but opposite in sign. For the longitudinal TFT, the current increases with tensile strain with a sensitivity $S_\epsilon(I_{D,l}) = 12.5$. In contrast, for the transverse TFT, this is small and negative $S_\epsilon(I_{D,t}) = -1.1$, clearly signifying an orientation dependence. The value of $S_\epsilon(I_{D,s}) = 4.5$ for the shear TFT can be explained from the linear superposition of the effects of longitudinal and transverse strain components.

The measured value for $S_\epsilon(I_{D,l})$ is close to the value of 15 ± 3 reported by Spear and Heintze [47.51] for intrinsic a-Si:H at room temperature. Gleskova et al. [47.60] have found a higher longitudinal sensitivity $S_\epsilon(I_{D,l}) = 26$. For the transverse sensitivity, Spear and Heintze have reported a positive value of $S_\epsilon(I_{D,t}) = 7$ for intrinsic a-Si:H samples.

Table 47.2 Values for $S_\epsilon^H(I_D)$, $S_\epsilon(\mu_{\text{eff}})$, and $S_\epsilon(V_{\text{thr}})$ for different orientations

Parameter	Longi- tudinal	Trans- verse	Shear
$S_\epsilon^H(I_D) = \Delta I_D / I_D \epsilon$	12.1	-1.1	4.5
$S_\epsilon(\mu_{\text{eff}}) = \Delta \mu_{\text{eff}} / \mu_{\text{eff}} \epsilon$	11	-1.1	4.0
$S_\epsilon(V_{\text{thr}}) = \Delta V_{\text{thr}} / V_{\text{thr}} \epsilon$	5	4.5	4.7

In addition to TFT orientation, we observe that the gate bias alters the magnitude of strain-induced change in current ΔI_D . To examine the impact of bias, deflection experiments were performed for different values of the gate bias V_{GS} in the range 4–20 V in 1 V steps. Figure 47.13 illustrates the measured $S_\epsilon(I_D)$ as a function of V_{GS} for TFTs of different orientations. Solid symbols denote measurement data for the linear regime ($V_{DS} = 0.5 \text{ V}$) while the open symbols are those for the saturation regime where the gate and drain terminals are shorted. Interestingly, the modulation in the current shifts toward positive values as the gate bias decreases. This is true for TFTs of all orientations, and independent of whether the devices were integrated on glass or silicon substrates.

However, the sensitivity $S_\epsilon(I_{D,t})$ for the transverse TFT undergoes a sign change. At high biases, the $S_\epsilon(I_{D,t})$ is generally small and negative (i.e. ΔI_D is positive for tensile strain). As the gate bias decreases, the $S_\epsilon(I_{D,t})$ virtually vanishes at approximately 7 V, and subsequently increases to a sizable positive value (i.e. ΔI_D is negative for tensile strain) at lower voltages ($V_{GS} < 7 \text{ V}$).

From the results of Fig. 47.13, we identify two distinct components underlying the strain-induced modulation of current: the high-bias ($V_{GS} > 7 \text{ V}$) $S_\epsilon^H(I_D)$ and low-bias ($V_{GS} < 7 \text{ V}$) $S_\epsilon^L(I_D)$ components such that

$$S_\epsilon(I_D) = S_\epsilon^H(I_D) + S_\epsilon^L(I_D). \quad (47.30)$$

At high biases, $S_\epsilon(I_D)$ of longitudinal, transverse, and shear TFTs gradually approach constant values. As seen from Table 47.2, the extracted values for $S_\epsilon^H(I_D)$ are strongly orientation dependent, suggesting the presence of strain-induced modulation in carrier mobility, whose sensitivity we define as $S_\epsilon(\mu_{\text{eff}}) = \Delta \mu_{\text{eff}} / \mu_{\text{eff}} \epsilon$. The mobility change in the longitudinal orientation is higher than that in the transverse orientation.

Superimposed on the high-bias component is the low-bias component $S_\epsilon^L(I_D)$ which manifests itself as a bias-dependent positive shift in $S_\epsilon(I_D)$. This component can be attributed to the modulation in threshold voltage. Correspondingly, we define the threshold-voltage sensitivity as $S_\epsilon(V_{\text{thr}}) = \Delta V_{\text{thr}} / V_{\text{thr}} \epsilon$. The change in V_{thr} can be attributed to a strain-induced change in the density of deep states, which is orientation independent [47.51]. The modulation in threshold voltage leads to a significant change in current at low biases, and can be quantitatively explained by looking at the current–voltage relation in the linear regime. From (47.16) and using partial differentiation with respect to

strain, we can write $S_\epsilon(I_{DS,lin})$ as

$$S_\epsilon(I_{DS,lin}) = S_G + S_\epsilon(\mu_{eff}) - S_\epsilon(V_{thr}) \frac{\alpha V_{thr}}{V_{GT}} + S_\epsilon(\alpha) \left(\alpha \ln \left| \frac{V_{GT}}{V_0} \right| - \frac{\alpha}{2} - \frac{1}{\alpha-1} \right), \quad (47.31)$$

where $V_0 = (2\epsilon k_B T_i N_0)^{1/2} / C_i$, and

$$S_G = S_\epsilon(W) - S_\epsilon(L) + (\alpha - 1)S_\epsilon(C_i)$$

Here, S_G includes the effect of change in device dimensions. The other terms on the right-hand side of (47.31), in order from the left, describe the dependence of $S_\epsilon(I_{DS,lin})$ on $S_\epsilon(\mu_{eff})$, $S_\epsilon(V_{thr})$, and $S_\epsilon(\alpha)$, respectively, which represent strain-induced modulation of the different TFT parameters (μ_{eff} , V_{thr} , and α).

As seen in (47.31), the modulation in mobility $S_\epsilon(\mu_{eff})$ is directly reflected in the change of current. In contrast, the strain-induced change in threshold voltage $\Delta V_{thr}/V_{thr}$ is scaled, and by a factor of $\alpha V_{thr}/V_{GT}$. This is particularly visible at low biases and its effect decreases with increasing gate bias V_{GT} . Thus, at high biases, the impact of threshold-voltage modulation is minimal, which yields

$$S_\epsilon^H(I_D) = S_G + S_\epsilon(\mu_{eff}). \quad (47.32)$$

In contrast, the low-bias component can be written as

$$S_\epsilon^L(I_D) = -S_\epsilon(V_{thr}) \frac{\alpha V_{thr}}{V_{GT}}. \quad (47.33)$$

It is important to note that the last term on the right-hand side of (47.31) represents the impact of strain-induced

modulation of α . This term contains a bias-dependent scaling factor of $\alpha \ln |V_{GT}/V_0|$, which does not correlate with the observed bias dependence of $S_\epsilon(I_D)$ seen in Fig. 47.13. This implies that modulation in V_{thr} and μ_{eff} are the dominant contributors to the observed changes in current.

The activation energy for the temperature dependence of $S_\epsilon^L(I_D)$ and $S_\epsilon^H(I_D)$ is defined as

$$E_i = \frac{\partial S_\epsilon^i(I_D)}{\partial (1/k_B T)} \text{ with } i = H \text{ or } L. \quad (47.34)$$

The values for E_H and E_L are found to be 140 meV and 0.58 eV, respectively. The much lower activation energy (140 meV) at high biases indicates that the $S_\epsilon^H(I_D)$ stems from the shallow states in the conduction-band tail. Again, this corroborates our previous findings that the sensitivity of the current at high biases is associated with the mobility modulation that is principally determined by the tail states. Spear and Heintze [47.51] have found an activation energy of 0.52 eV for intrinsic and doped a-Si:H layers. This corroborates with our low-voltage sensitivity data. The high activation energy for $S_\epsilon^L(I_D)$ identifies the role of deep states in the gap, which is in agreement with our previous finding that $S_\epsilon(I_D) \propto S_\epsilon(V_{thr})$ at low biases. Here, the strain is believed to modify the energy of the deep states [47.51].

From (47.32) and (47.33), the values of $S_\epsilon(\mu_{eff})$ and $S_\epsilon(V_{thr})$ for different orientations can be determined (Table 47.2). The values can be incorporated in a compact model for the different TFT orientations, which can be used for computer-aided design (CAD) of mechanically flexible TFT circuits [47.61].

48. Photoconductors for X-Ray Image Detectors

Recent flat-panel X-ray imaging detectors have been shown to be able to replace present-day X-ray film/screen cassettes; they capture an X-ray image electronically and hence enable a clinical transition to digital radiography. This chapter critically discusses the material, transport and imaging detector properties (e.g., dark current) of several potential X-ray photoconductors and compares them with an ideal photoconductor for use in direct-conversion imaging detectors. The present chapter also considers various metrics of detector performances including sensitivity, detective quantum efficiency, resolution in terms of the modulation transfer function, image lag and ghosting; and examines how these metrics

depend on the photoconductor, and detector structure and design.

The flat-panel X-ray image detector (sensor) concept is illustrated in Fig. 48.1 where X-rays passing through the patient's hand are incident on a sensor. The sensor converts the incident image to a digital image that can be sent to a computer and viewed on a monitor. Research over the past ten years [48.1] has indicated that the most practical flat-panel medical digital radiographic systems (mammography, chest radiography and fluoroscopy) are those based on a large-area inte-

Fig. 48.1 Schematic illustration of an active matrix flat-panel imaging (AMFPI) system used for X-ray imaging

grated circuit or active matrix array (AMA). Flat-panel imagers incorporating active matrix arrays are called active matrix flat-panel imagers or AMFPI. Active matrix arrays using hydrogenated amorphous silicon (a-Si:H) thin-film transistors (TFTs) have been shown to be practical pixel-addressing systems for displays [48.2]. These a-Si:H arrays can be converted into X-ray-sensitive imaging devices by adding a thick (0.1–1 mm) X-ray-detecting medium, either a phosphor or a photoconductor. The physical form of the X-ray AMFPI is similar to a film/screen cassette and thus it will easily fit into current medical film/screen-based X-ray imaging systems. The X-ray image is stored and displayed on the computer almost immediately after the X-ray exposure. The stored image can be rapidly transmitted to remote locations for consultation and analysis. The dynamic range of recently developed AMFPI systems is much higher than film/screen-based imaging systems [48.3]. AMFPI are able to read out an entire image in 1/30 s, sufficiently rapid to perform fluoroscopy (real-time imaging) [48.4].

The active matrix array used for pixel addressing and readout in an AMFPI consists of many single pixels, each of which represents a corresponding pixel of the image. Each pixel collects charge proportional to the X-ray radiation that it receives. To generate this signal charge, either a phosphor converts the X-rays

Fig. 48.2 Schematic diagram that shows some pixels of the active matrix array for use in X-ray AMFPI with self-scanned electronic readout. The charge distribution residing on the panel's pixels are read out by scanning the arrays row by row using peripheral electronics and multiplexing the parallel columns into a serial digital signal

to visible light, which in turn is detected with a pin photodiode at the pixel (indirect) or an X-ray photoconductor converts the incident X-rays to charge (direct) in one step. For both the indirect and direct conversion approaches, the latent image is a charge distribution residing on the array's pixels. The charges are read out by scanning the arrays row by row using peripheral electronics and multiplexing the parallel columns into a serial digital signal. This signal is then transmitted to a computer system for storage and display. Several manufacturers and academic researchers have used the indirect approach [48.5, 6]. However, we believe that the direct approach, due to its higher conversion gain, has the potential to produce systems superior in image quality to indirect conversion sensors and be both easier and cheaper to manufacture due to their simpler structure. This chapter considers only the direct-conversion X-ray imager and how its dark current, sensitivity, resolution and detective quantum efficiency (DQE) depend on the photoconductor and detector structure. This chapter also discusses essential photoconductor properties, charge transport and imaging properties of promising photoconductors.

Active matrix arrays allow a monolithic imaging system of large area (e.g. 40 cm × 40 cm) to be constructed. As for conventional integrated circuits, planar processing of the array through deposition and doping of lithographically masked individual layers of metals, insulators and semiconductors implement the design of active matrix arrays. In the future, even larger areas should become feasible if required. Millions of individual pixel electrodes in the matrix and are connected, as shown in Fig. 48.2. Each pixel has its own thin-film transistor (TFT) switch and storage capacitor to store image charges. The TFT switches control the image charge so that one line of pixels is activated electronically at a time. Normally, all the TFTs are turned off, permitting the latent image charge to accumulate on the array. The readout is achieved by external electronics and software controlling the state of the TFT switches. The active matrix array consists of $M \times N$ (e.g. 2480 × 3072) storage capacitors C_{ij} whose stored image charge can be read through properly addressing the TFT (i, j) via the gate (i) and source (j) lines. The charges read on each C_{ij} are converted to a digital image. The image readout technique is described by Rowlands and Kasap [48.7]. The readout is self-scanning in that no external means such as a laser are used. The scanning is part of the AMFPI electronics and software, thus permitting a truly compact device.

Fig. 48.3 Cross section of a single pixel (i, j) with a TFT switch. The top electrode (A) on the photoconductor is a vacuum-coated metal (e.g. Al). The bottom electrode (B) is the pixel electrode that is one of the plates of the storage capacitance (C_{ij}). (Not to scale—the TFT height is highly exaggerated)

To construct a direct-conversion X-ray AMFPI, a large-band-gap (> 2 eV) high-atomic-number semiconductor or X-ray photoconductor (e.g., stabilized amorphous selenium, a-Se) layer is coated onto the active matrix array. An electrode (A) is subsequently deposited onto the photoconductor layer to facilitate the application of a biasing potential and, hence, an electric field F in the photoconductor layer as shown in Fig. 48.3. The biasing potential applied to the radiation receiving electrode A (top electrode) may be positive or negative, the selection of which depends on many factors discussed later in this chapter. The applied bias varies from a few hundred to several thousand Volts. The capacitance C_{pc} of the photoconductor layer over the pixel is in series with, and much smaller than, the pixel capacitance C_{ij} attached to the pixel electrode, so that most of the applied potential is dropped across the photoconductor and not across the pixel capacitance. The electron-hole pairs (EHPs) generated in the photoconductor by the absorption of X-ray photons travel along the field lines and are collected by the electrodes. If the applied bias voltage is positive, then electrons collect at the positive bias electrode and holes accumulate on the storage capacitor C_{ij} . Each pixel electrode carries an amount of charge Q_{ij} proportional to the

amount of incident X-ray radiation in the photoconductor layer over that pixel, which can be read during self-scanning.

The selection of the photoconductor material for use in direct-conversion X-ray image detectors is currently an important research field in electronic materials. There are various competing semiconductors, such as amorphous (a-)Se, HgI_2 , $CdZnTe$, PbI_2 , PbO and $TlBr$. Detectors based on a-Se have already been developed and some have been commercialized for mammography, general radiography and fluoroscopy [48.8] with active areas as large as $43\text{ cm} \times 43\text{ cm}$. This chapter critically discusses charge-transport and imaging-detector properties (e.g., dark current and image lag) of these photoconductors and compares them with an ideal photoconductor for X-ray imaging detectors. The present chapter also examines various imaging characteristics of photoconductor-based X-ray AMFPIs, including sensitivity (S), detective quantum efficiency (DQE), resolution in terms of the modulation transfer function (MTF), image lag and ghosting. We examine how these characteristics depend not only on the photoconductor's charge-transport properties but also on the detector structure, i.e., the size of the pixel and the thickness of the photoconductor.

48.1 X-Ray Photoconductors

48.1.1 Ideal Photoconductor Properties

The performance of direct-conversion X-ray detectors depends critically on the selection and design of the photoconductor. It is therefore instructive to identify what constitutes a nearly ideal X-ray photoconductor to guide a search for improved performance or a better material. Ideally, the photoconductive layer should possess the following material properties:

1. Most of the incident X-ray radiation should be absorbed within a practical photoconductor thickness to avoid unnecessary patient exposure. This means that, over the energy range of interest, the absorption depth δ of the X-rays must be substantially less than the device layer thickness L . In other words, the quantum efficiency (η) should be high.
2. The photoconductor should have high intrinsic X-ray sensitivity, i.e., it must be able to generate as many collectable (free) electron-hole pairs (EHPs) as possible per unit of incident radiation. This means

the amount of radiation energy required, denoted by W_{\pm} , to create a single free electron-hole pair must be as low as possible. Typically, W_{\pm} increases with the band gap E_g of the photoconductor [48.9] and thus a low E_g is desired for maximum X-ray sensitivity.

3. There should be little bulk recombination of electrons and holes as they drift to the collection electrodes; EHPs are generated in the bulk of the photoconductor. Bulk recombination is proportional to the product of the concentration of holes and electrons, and typically it is negligible for clinical exposure rates (i.e. provided the instantaneous X-ray exposure is not too high).
4. There should be negligible deep trapping of EHPs, which means that, for both electrons and holes, the schubweg defined as $\mu\tau F \gg L$ where μ is the drift mobility, τ is the deep-trapping time (lifetime), F is the electric field and L is the photoconductor layer thickness. The schubweg is the mean distance a carrier drifts before it is trapped and unavailable for

- conduction. The temporal responses of the X-ray image detector, such as lag and ghosting, depend on the rate of carrier trapping.
5. The diffusion of carriers should be negligible compared with their drift. This property ensures less time for lateral carrier diffusion and leads to better spatial resolution.
 6. The dark current should be as small as possible, because it is a source of noise. This means the contacts to the photoconductor should be non-injecting and the rate of thermal generation of carriers from various defects or states in the band gap should be negligibly small (i. e. dark conductivity is practically zero). Small dark conductivity generally requires a wide-band-gap semiconductor, which conflicts with condition (2) above. The dark current should preferably not exceed 10–1000 pA/cm², depending on the clinical application [48.10].
 7. The longest carrier-transit time, which depends on the smallest drift mobility, must be shorter than the image readout time and inter-frame time in fluoroscopy.
 8. The properties of the photoconductor should not change with time because of repeated exposure to X-rays, i. e. X-ray fatigue and X-ray damage should be negligible.
 9. The photoconductor should be easily coated onto the AMA panel (typically 30×30 cm and larger), for example, by conventional vacuum techniques without raising the temperature of the AMA to damaging levels (e.g., ≈ 300 °C for a-Si panels). This eliminates the possibility of using single-crystal materials that would require extended exposure to much higher temperature if they were to be grown directly onto the panel.
 10. The photoconductor should have uniform characteristics over its entire area.
 11. The temporal artifacts such as image lag and ghosting should be as small as possible. Lag is the carryover of image charge generated by previous X-ray exposures into subsequent image frames. The residual signal fractions following a pulsed X-ray irradiation are referred to as “image lag”. Ghosting is the change of X-ray sensitivity of the X-ray image detector as a result of previous exposure to radiation. In the presence of ghosting, a shadow impression of a previously acquired image is visible in subsequent uniform exposures.

The large-area-coating requirement in (9) rules out the use of crystalline semiconductors, whose only practi-

cal production process is to grow large boules, which are subsequently sliced. Thus, only amorphous or polycrystalline (poly) photoconductors are currently practical for use in large-area X-ray imaging detectors. Amorphous selenium (a-Se) is one of the most highly developed photoconductors for large-area detectors due to its commercial use in photocopiers and laser printers as an electrophotographic photoreceptor [48.11]. In fact, the direct-conversion flat-panel imaging technology has been made possible by the use of two key elemental amorphous semiconductors: a-Si:H (used for TFTs) and a-Se (used for photoconductor layers). Although their properties are different, both can be readily prepared in large areas, which is essential for an X-ray imaging detector. Stabilized a-Se (a-Se alloyed with 0.2–0.5% As and doped with 10–40 ppm Cl) is currently the preferred photoconductor for clinical X-ray image sensors, because it can be quickly and easily deposited as a uniform film over large areas and it has an acceptable X-ray absorption coefficient, good charge-transport properties for both holes and electrons, and lower dark current than many competing polycrystalline layers [48.9, 10]. Flat-panel X-ray image detectors with an a-Se photoconductor have been shown to provide excellent images.

There has been active research to find potential X-ray photoconductors to replace a-Se in flat-panel image detectors because of the substantially higher W_{\pm} and operating electric field of a-Se compared to other potential X-ray photoconductors [48.10, 12]. For example, the typical value of the electric field used in a-Se devices is 10 V/μm where the value of W_{\pm} is about 45 eV; the value of W_{\pm} is 5–6 eV for polycrystalline mercuric iodide (poly-HgI₂) and polycrystalline CdZnTe. The main drawback of polycrystalline materials is the adverse effects of grain boundaries in limiting charge transport and the nonuniform response of the sensor due to large grain sizes. Grain boundaries in the polycrystalline material are expected to create trapping levels within the band gap and introduce potential barriers between neighboring grains [48.13]. Another disadvantage of these polycrystalline detectors is the higher dark current compared to a-Se detectors. However, there have been efforts to improve the material properties and reduce the dark currents of polycrystalline HgI₂ and poly-CdZnTe-based image detectors [48.14, 15]. Recent experiments on large-area HgI₂, PbI₂, CdZnTe (< 10% Zn), and PbO polycrystalline X-ray photoconductive layers deposited on active matrix arrays have shown encouraging results [48.16–18]. A more detailed description of these three potential photoconductors for

direct-conversion AMFPIs is presented below along with TlBr.

48.1.2 Potential Photoconductors

The properties of an ideal photoconductor for X-ray image detectors have been discussed in the section above. In this section, important properties of potential photoconductors for X-ray image detectors are discussed and compared with the ideal case.

Amorphous Selenium (a-Se)

Stabilized a-Se can be easily coated as thick films (e.g., 100–1000 μm) onto suitable substrates by conventional vacuum deposition techniques and without the need to raise the substrate temperature beyond 60–70°C (much below the damage threshold of the AMA, e.g., $\approx 300^\circ\text{C}$ for a-Si:H panels). Its amorphous state maintains uniform characteristics to a very fine scale over large areas. Stabilized a-Se, not pure a-Se, is used in X-ray sensors, because pure a-Se is thermally unstable and crystallizes over several weeks or months following manufacture. Crystalline Se is unsuitable as an X-ray photoconductor because it has a much lower dark resistivity and hence orders of magnitude larger dark current

than a-Se. Alloying pure a-Se with As (0.2–0.5% As) greatly improves the stability of the composite film and helps to prevent crystallization. However, it is found that the addition of As has an adverse effect on the hole lifetime because the arsenic introduces deep hole traps. If the alloy is doped with 10–20 parts per million (ppm) of a halogen (such as Cl), the hole lifetime is restored to its initial value. Thus, a-Se film that has been alloyed with 0.2–0.5% As (nominal 0.3% As) and doped with 10–20 ppm Cl is called stabilized a-Se. The density of a-Se is 4.3 g/cm^3 with an energy gap of $E_g \approx 2.1\text{--}2.2\text{ eV}$.

There are localized states in the so-called forbidden gap of a-Se. Some of these are located near the band edges (shallow traps), while some are located deep in the energy band (deep traps). Localized states are simply traps and are not extended throughout the material, but are localized in space (both shallow and deep) due to various structural defects that are stable at room temperature. Drift of both electrons and holes involves interactions with shallow and deep traps, as shown in Fig. 48.4. Shallow traps reduce the drift mobility; deep traps prevent the carriers from crossing the photoconductor. The effective drift mobility μ of carriers is the mobility μ_0 in the extended states reduced by the trapping and release events due to the presence of shallow traps,

$$\mu = \frac{\tau_c}{\tau_c + \tau_r} \mu_0, \quad (48.1)$$

where τ_c and τ_r are the average capture and release times in the shallow-trap centers. The capture time represents the mean time that a mobile carrier drifts in the extended states before becoming trapped in a shallow-trap center. The release time is the mean time that a carrier remains in a trap before being released back into the extended states. Re-emission from a shallow trap is mostly dominated by thermally activated processes. The shallow-trap release time is relatively short and a typical carrier may experience many shallow capture and release events while traversing the detector thickness (100–1000 μm).

Although the nature of the shallow traps in a-Se has not been fully established, the drift mobilities of both holes and electrons are quite reproducible. The room-temperature effective hole mobility μ_h is independent of the preparation of the sample and has a value of $\approx 0.12\text{ cm}^2/\text{Vs}$, whereas the effective electron mobility μ_e is in the range $0.003\text{--}0.006\text{ cm}^2/\text{Vs}$ [48.12]. The hole drift mobility does not change with the addition of As or Cl. The value of μ_e decreases with the addition of

Fig. 48.4 Diagram illustrating the band gap of a photoconductor with an applied electric field that tilts the bands, encouraging drift of holes in the direction of the field and electrons counter to the field. Drift of both electrons and holes involves interactions with shallow and deep traps. Shallow traps reduce the drift mobility and deep traps prevent the carriers from crossing the photoconductor

As to a-Se (e.g., in stabilized a-Se) but Cl doping does not affect it.

Once a carrier is caught in a deep trap, it will remain immobile until a lattice vibration gives it enough energy to be excited back into the extended states, where it can drift once again. The deep-trap release time is very long (minutes to hours), and a deeply trapped carrier is essentially permanently removed from conduction. Therefore, the carrier lifetime depends on the concentration of deep rather than shallow traps. The charge-carrier lifetimes vary substantially between different samples and depend on factors such as the source of a-Se material, impurities, and the preparation method. The electron lifetime τ_e is particularly sensitive to impurities in the a-Se source material. The hole lifetime τ_h drops rapidly with decreasing substrate temperature (temperature of the a-Se substrate during the evaporation process) whereas τ_e is unaffected. Increasing the As concentration in a-Se decreases τ_h and increases τ_e [48.19]. On the other hand, Cl doping increases τ_h and decreases τ_e . The typical lifetimes in stabilized a-Se are in the range 10–500 μ s for holes and 100–1500 μ s for electrons [48.12].

The fractional increase in the τ_e with As addition is greater than the drop in μ_e . Thus the electron range ($\mu_e \tau_e$) increases with As content. The effect of Cl doping on the carrier ranges ($\mu \tau$ products) is more pronounced than that of As doping. Thus, we can control both electron and hole ranges by appropriately choosing the relative amounts of As and Cl in a-Se.

The electron-hole-pair creation energy W_{\pm} in a-Se has a strong dependence on electric field F but only a weak dependence on the X-ray photon energy E [48.20, 21]. The quantity W_{\pm} is decreased by increasing either F or E . W_{\pm} at a given E in a-Se follows an empirical relation given by

$$W_{\pm} \approx W_{\pm}^0 + \frac{B(E)}{F^n}, \quad (48.2)$$

where $B(E)$ is a constant that depends on E , W_{\pm}^0 is the saturated EHP creation energy (at infinite F), and n is typically in the range 0.7–1 [48.22]. The value of W_{\pm}^0 should be $2.2E_g + E_{\text{phonon}}$ [48.23], where E_{phonon} is the phonon energy. With $E_g \approx 2.1$ eV and $E_{\text{phonon}} < 0.5$ eV, we would expect that $W_{\pm}^0 \approx 5$ eV. The energetic primary electron generates many EHPs but only a certain fraction of these are free to drift and the rest recombine before they can contribute to the photocurrent. There are various possible explanations for the F dependence of the EHP creation energy. First, the simultaneously generated electron and its hole twin are attracted to each other by their mutual Coulombic force and may even-

Fig. 48.5 A multilayer pin-type a-Se device structure for blocking dark current

tually recombine. This type of recombination is called geminate recombination (from Gemini—the twins). Another possible mechanism is columnar recombination that involves the recombination of nongeminate electrons and holes generated close to each other in the columnar track of the single high-energy electron (primary) created by the absorption of an X-ray. In both the geminate and columnar cases, the number of carriers escaping recombination should increase with increasing F , which acts to separate the oppositely charged carriers. The question of whether the F dependence of W_{\pm} in a-Se is dominated by geminate or columnar recombination has not been fully resolved and is currently an area of research [48.23, 24]. However, the energy dependence of W_{\pm} is better understood. It decreases slowly with increasing photon energy in the diagnostic [48.20] and megavolt range [48.25]. The total change in W_{\pm} from 20 keV to 6 MeV is of the order of three. This appears to be due to a reduction of recombination with increase in energy. The rate of deposition of energy per unit distance traveled by a primary electron decreases as a function of energy, decreasing the density of EHPs in the column around it. This is expected to reduce columnar recombination—as is seen. Thus it appears that at low energies the contribution from columnar recombination is approximately twice that from geminate, but at high enough energy the columnar effect is reduced to zero. The typical value of the F used in a-Se devices is 10 V/ μ m where the value W_{\pm} is 35–55 eV over the diagnostic beam energy (12–120 keV) and ≈ 15 eV at megavolt energies.

The dark resistivity of a-Se is $\approx 10^{14}$ Ω cm. The bulk-induced dark current in a-Se detectors is within the acceptable limit (< 1 nA/cm²) for $F \leq 20$ V/ μ m. However, the injected dark current for metal/a-Se/metal single-layer structures depends on the nature of the metal/a-Se contacts and nonlinearly on F . It has

however been possible to reduce the dark current to a negligible level in multilayer a-Se structures, e.g., ($< 0.1 \text{ nA/cm}^2$ at F as high as $20 \text{ V}/\mu\text{m}$ [48.26]) by use of blocking contacts. A pin (p-type–intrinsic–n-type) a-Se structure is shown in Fig. 48.5, where the thickness of both the p and n blocking contact layers is a few microns. These p- and n-layers are appropriately doped to serve as unipolar conducting layers that easily trap electrons and holes, respectively, but allow the transport of oppositely charged carriers. The rate of emission of these deeply trapped carriers is so small that there is no significant current injection into the bulk a-Se layer. With these n- and p-layers, the F at the metal electrodes is sufficiently small to minimize charge injection from the contacts, which substantially reduces the dark current.

The image lag in a-Se detectors is under 2% after 33 ms and less than 1% after 0.5 s in the fluoroscopic mode of operation [48.27]. Therefore, image lag in a-Se detectors is considered to be negligible. The pixel-to-pixel sensitivity variation is also negligible in a-Se detectors. The presampling MTF of these detectors is almost equal to the theoretical MTF (sinc function) determined by the pixel aperture [48.28].

Mercuric Iodide (HgI_2)

Poly- HgI_2 has been used as a photoconductor layer in X-ray image detectors. It has been prepared by either physical vapor deposition (PVD) or screen printing (SP) from a slurry of HgI_2 crystals using a wet particle-in-binder process [48.16]. There appears to be no technological barrier to preparing large-area layers, and direct-conversion X-ray AMFPI of $20 \times 25 \text{ cm}^2$ (1536×1920 pixels) and $5 \times 5 \text{ cm}^2$ (512×512 pixels) size have been demonstrated using PVD [48.16] and SP poly- HgI_2 layers. The prototype HgI_2 sensors can potentially be used for mammographic, fluoroscopic or radiographic imaging. There has been active research to improve the material properties of poly- HgI_2 -based image detectors including improving the nonuniformity by reducing the grain size. The band-gap energy $E_g = 2.1 \text{ eV}$, the ionization energy $W_{\pm} \approx 5 \text{ eV}$ and the density of poly- HgI_2 is 6.3 g/cm^3 . The resistivity of this material is $\approx 4 \times 10^{13} \Omega \text{ cm}$ [48.29].

The HgI_2 layer is deposited onto either conductive [indium-tin-oxide- (ITO) or gold-coated] glass plates or a-Si TFT arrays. HgI_2 tends to react chemically with most metals; hence a thin blocking layer (typically, $\approx 1 \mu\text{m}$ layer of insulating polymer) is used between the HgI_2 layer and the pixel electrodes to prevent the reaction and also to reduce the dark current. The HgI_2 layer thickness varies in the range

$100\text{--}500 \mu\text{m}$ and the grain size is $20\text{--}60 \mu\text{m}$. Several hundred angstroms of palladium (Pd) or Au are deposited (by direct evaporation) on top of the HgI_2 layer followed by a polymer encapsulation layer to form a bias electrode.

The dark current of HgI_2 imagers increases super-linearly with the applied bias voltage. For PVD HgI_2 detectors the dark current depends strongly on the operating temperature. It increases by a factor of about two for each 6°C of temperature rise. It is reported that the dark current varies from $\approx 2 \text{ pA/mm}^2$ at 10°C to $\approx 180 \text{ pA/mm}^2$ at 35°C at $F = 0.95 \text{ V}/\mu\text{m}$, which is not desirable for medical imagers (the maximum dark current for medical imaging should be $< 10 \text{ pA/mm}^2$). Therefore, PVD HgI_2 imagers should be operated at relatively low bias (preferably less than $\approx 0.5 \text{ V}/\mu\text{m}$) and relatively low temperature ($< 25^\circ\text{C}$). The dark current in the SP sample is an order of magnitude smaller than in the PVD sample and more stable against temperature variation. It is possible to keep the dark current below 10 pA/mm^2 at temperatures up to 35°C and $F = 1 \text{ V}/\mu\text{m}$. A major disadvantage of SP detectors is that they show 2–4 times less sensitivity compared to PVD detectors.

Electrons have much longer range than holes in HgI_2 and thus the receiving electrode is negatively biased to obtain a higher sensitivity. The $\mu_e\tau_e$ for electrons in the SP HgI_2 is in the range $10^{-6}\text{--}10^{-5} \text{ cm}^2/\text{V}$ [48.16, 30], and $\mu_e\tau_e$ in the PVD sample is about an order of magnitude greater. Recently it was reported that $\mu_e\tau_e$ in PVD HgI_2 is in the range $10^{-5}\text{--}10^{-4} \text{ cm}^2/\text{V}$, which is almost equal to that of single-crystal HgI_2 [48.14, 31]. The reason is that the PVD HgI_2 layer grows in a columnar structure perpendicular to the substrate. Thus a charge carrier may drift along a column without having to pass through grain boundaries, where it would encounter excess trapping and/or recombination. Samples with larger grain sizes may have fewer grain-boundary defects. Hence there is a trend of increasing $\mu_e\tau_e$ with grain size in the PVD samples. However, this trend is not observed in the SP sample, which indicates another mechanism is responsible for its low $\mu_e\tau_e$. Larger grain sizes may cause nonuniform sensor response. The grain sizes must be much smaller than the pixel size to get a uniform response. $\mu_h\tau_h$ in poly- HgI_2 is of the order $\approx 10^{-7} \text{ cm}^2/\text{V}$ [48.30].

Two important drawbacks of polycrystalline sensors are the image lag and the pixel-to-pixel sensitivity variation or nonuniform response. The lowest image-lag characteristics reported are $\approx 7\%$ first-frame lag, $\approx 0.8\%$ after 1 s and $\approx 0.1\%$ at 3 s in fluoroscopic

mode (15 frames/s). The pixel-to-pixel sensitivity variation reduces the dynamic range of the imagers. The relative standard deviation of the sensitivity (standard deviation/average value) in the latest HgI₂ AMFPI is $\approx 10\%$. It is reported that HgI₂ image detectors with smaller grain sizes show good sensitivity and also an acceptably uniform response. The presampling MTF of these detectors is almost equal to the theoretical MTF (sinc function) determined by the pixel aperture.

Cadmium Zinc Telluride (CdZnTe)

CdZnTe ($< 10\%$ Zn) polycrystalline film has been used as a photoconductor layer in X-ray AMFPI. CdZnTe is commonly called CZT. Although CZT can be deposited on large areas, direct-conversion AMFPI of only $7.7 \times 7.7 \text{ cm}^2$ (512×512 pixels) have been demonstrated using polycrystalline CZT (poly-CZT). The CZT layer thickness varies in the range $200\text{--}500 \mu\text{m}$. Temporal lag and nonuniform response were noticeable in early CZT sensors. Large and nonuniform grain sizes are believed to be responsible for the temporal lag and nonuniform response of the sensor. Recent studies show that Cl doping makes a finer, more uniform grain structure [48.15]. The ionization energy $W_{\pm} \approx 5 \text{ eV}$, and the density of band gap Cd_{0.95}Zn_{0.05}Te is 5.8 g/cm^3 . The band gap energy E_g of Cd_{0.95}Zn_{0.05}Te is 1.7 eV and the resistivity of this material is $\approx 10^{11} \Omega \text{ cm}$ [48.32].

Typically CZT is first coated onto an inert substrate and then attached to the active matrix array. The advantage of this technique is that the electrical properties and hence imaging performances of the detector can be optimized without causing any thermal or chemical damage to the TFT array. The CZT film is deposited by the close-spaced sublimation method [48.33] onto an alumina (Al₂O₃) substrate coated with ITO, which forms the bias (top) electrode. A cross section of the poly-CZT detector is shown in Fig. 48.6. The several-

microns-thick ZnTe layer acts as a barrier to electron injection and hence suppresses dark current under the negative bias. This ZnTe layer is omitted for the positive bias. Conducting resin bumps on the pixel electrodes connect each pixel to the CZT layer.

Introduction of Zn into the CdTe lattice increases the band gap, decreases the conductivity and hence reduces the dark current. In CZT μ_h decreases with increasing Zn concentration whereas μ_e remains nearly constant. Again, addition of Zn to CdTe increases lattice defects and hence reduces carrier lifetimes. The poly-CZT has a lower density, which results in a lower quantum efficiency η than its single-crystal counterpart. Although (for a detector of given thickness) X-ray sensitivity in CZT detectors is lower than in CdTe detectors, the CZT detectors show a better signal-to-noise ratio and hence give a better DQE. The measured sensitivities are higher than a-Se.

The dark current of Cd_{0.95}Zn_{0.05}Te imagers increases almost linearly with F and is $\approx 70 \text{ pA/mm}^2$ at $F = 0.25 \text{ V}/\mu\text{m}$ [48.17], which makes it unsuitable for applications requiring long exposure times. The dark current would be expected to decrease with increasing Zn concentration due to the increased E_g . This has in fact, been demonstrated [48.15], i.e., the dark current in Cd_{0.92}Zn_{0.08}Te sensors is 40 pA/mm^2 at $F = 0.4 \text{ V}/\mu\text{m}$.

The mobility-lifetime products of both electrons and holes in poly-CZT are less than in single-crystal CZT. The values of $\mu\tau$ in single-crystal Cd_{0.9}Zn_{0.1}Te are in the range $10^{-4}\text{--}10^{-3} \text{ cm}^2/\text{V}$ (electrons) and $10^{-6}\text{--}10^{-5} \text{ cm}^2/\text{V}$ (holes) [48.34]. But the values of $\mu\tau$ in poly-Cd_{0.95}Zn_{0.05}Te are $\approx 2 \times 10^{-4} \text{ cm}^2/\text{V}$ (electrons), and $\approx 3 \times 10^{-6} \text{ cm}^2/\text{V}$ (holes) [48.35, 36]. Since $\mu_e\tau_e \gg \mu_h\tau_h$ in CZT, negative bias to the radiation-receiving electrode is the preferred choice for better sensitivity and temporal response.

The relative standard deviation of the sensitivity (standard deviation/average value) in the latest CZT AMFPI is $\approx 20\%$ [48.15]. The image-lag characteristics reported are $\approx 70\%$ first-frame lag, $\approx 20\%$ after three frames and 10% at 1 s in fluoroscopic mode (30 frames/s). In single-pulse radiographic mode the first-frame lag is less than 10% [48.15]. The longer image-lag characteristics of CZT sensors in fluoroscopic mode imply that it is not yet suitable for fluoroscopic applications. The presampling MTF of CZT detector is ≈ 0.3 ($150\text{-}\mu\text{m}$ pixel size) at the Nyquist frequency f_N (theoretical MTF, sinc function, is ≈ 0.64 at $f_N = 3.3 \text{ line pairs per mm}$), where the MTF of CsI imagers is less than 0.2 [48.17].

Fig. 48.6 Cross section of the polycrystalline CZT detector structure (after Tokuda et al. [48.15])

Lead Iodide (PbI₂)

PbI₂ polycrystalline photoconductive layers have been prepared using PVD at a substrate temperature of 200–230 °C. A deposition of several hundred angstroms of palladium (Pd) is used to form a top electrode. Grains are described as hexagonal platelets with the longest dimensions being 10 μm or less. The platelets grow perpendicular to the substrate, producing films that are less dense (3–5 g/cm³) than bulk crystalline material (6.2 g/cm³). There appears to be no technological barrier to preparing large-area layers, and direct-conversion AMFPI of 20×25 cm² size (1536×1920 pixels) have been demonstrated [48.37]. Coating thickness varies in the range 60–250 μm and prototype PbI₂ imagers have been used for radiographic imaging [48.37]. The band-gap energy $E_g = 2.3$ eV, and the ionization energy $W_{\pm} \approx 5$ eV. The resistivity of this material is in the range $10^{11} - 10^{12}$ Ω cm.

Lead iodide detectors have a very long image-lag decay time. The image lag depends on the exposure history. The image-lag characteristics reported are $\approx 75\%$ first-frame lag, $\approx 15\%$ after 3 s in fluoroscopic mode (15 frames/s), whereas in single-pulse radiographic mode the first-frame lag is less than 50% and drops below 1% within 1 s [48.37]. The long image-lag characteristics of PbI₂ in fluoroscopic mode imply that it is unsuitable for fluoroscopic applications.

The dark current of PbI₂ imagers increases sublinearly with the applied bias voltage. The dark current is in the range 10–50 pA/mm² at $F = 0.5$ V/μm, much higher than PVD HgI₂ detectors, making it

unsuitable for long-exposure-time applications. The presampling MTF is ≈ 0.35 (127 μm pixel size) at f_N (theoretical MTF, sinc function, is ≈ 0.64 at $f_N = 3.93$ lp/mm), where the MTF of CsI imagers is less than 0.2 [48.37]. The resolution of PbI₂ imagers is acceptable but slightly worse than that of HgI₂ imagers. Also, the X-ray sensitivity of PbI₂ imagers is lower than that of HgI₂ imagers. The pixel-to-pixel sensitivity variation in PbI₂ imagers is substantially lower.

The $\mu\tau$ product of holes and electrons in PVD PbI₂ are 1.8×10^{-6} cm²/V and 7×10^{-8} cm²/V, respectively [48.37]. μ_h in poly-PbI₂ is in the range 0.02–0.15 cm²/Vs whereas μ_h in single-crystal PbI₂ is 2 cm²/Vs [48.38]. This indicates that μ_h in poly-PbI₂ is controlled by shallow traps, probably introduced at the grain boundaries.

Lead Oxide (PbO)

The large-area deposition requirement is compatible with the use of polycrystalline PbO (poly-PbO) film as a photoconductor layer in AMFPI. Direct-conversion flat-panel X-ray imagers of 18×20 cm² (1080×960 pixels) from a poly-PbO with film thicknesses of ≈ 300 μm have been demonstrated [48.18]. One advantage of PbO over other X-ray photoconductors is the absence of heavy-element K-edges for the entire diagnostic energy range up to 88 keV, which suppresses additional noise and blurring due to the K-fluorescence. The ionization energy $W_{\pm} \approx 8$ eV and the density of poly-PbO is 9.6 g/cm³. The band-gap energy E_g of PbO

Table 48.1 Material properties

Photoconductor, state and preparation	E_g (eV)	W_{\pm} (eV)	Density (g/cm ³)	Resistivity (Ω cm)	Electrons μ_e (cm ² /Vs), $\mu_e \tau_e$ (cm ² /V)	Holes μ_h (cm ² /Vs) $\mu_h \tau_h$ (cm ² /V)

PbO, polycrystalline	≈ 1.0	40 at 3 V/ μm field	3–8% after 1 s	?
TlBr, polycrystalline	≈ 1.0	?	?	?

is 1.9 eV and the resistivity of this material is in the range $(7\text{--}10)\times 10^{12} \Omega \text{ cm}$ [48.18].

Lead oxide photoconductive polycrystalline layers have been prepared by thermal evaporation in a vacuum chamber at a substrate temperature of $\approx 100^\circ\text{C}$. An evaporated layer of Al, Au or Pd was used to form a top electrode of thickness 100–200 nm [48.39]. The PbO layer consists of very thin platelets of a few microns thickness and has a density of $\approx 50\%$ of the single-crystal density. PbO slowly degrades if it is exposed to air under normal ambient temperature but a few hours exposure is acceptable. However, in the long term PbO reacts with water and CO₂ causing an increase in dark current and a decrease in X-ray sensitivity. Therefore, a polymer or a semiconductor (e.g., doped a-Se) passivation layer is used to prevent exposure to the atmosphere. This is usually placed between the photoconductor layer and the top metal electrode. The passivation layer avoids degradation of the PbO layer and reduces the dark current [48.39]. The dark current in PbO sensors is $\approx 40 \text{ pA}/\text{mm}^2$ at $F = 3 \text{ V}/\mu\text{m}$ [48.18]. $\mu_e\tau_e$ in poly-PbO is $\approx 5\times 10^{-7} \text{ cm}^2/\text{V}$ [48.18]. The lag signal in fluoroscopic mode is in the range 3–8% after 1 s. The presampling MTF of PbO detector is ≈ 0.5 (184 μm pixel size) at f_N (theoretical MTF, sinc function, is ≈ 0.64 at $f_N = 2.72 \text{ lp}/\text{mm}$) [48.18].

Thallium Bromide (TlBr)

Polycrystalline thallium bromide (poly-TlBr) has not yet been used in an AMFPI but has been used in a large-area (9-inch-diameter) direct-conversion detector called

an X-ray-sensitive electron-beam image tube (XEBIT). The operational principle of the XEBIT is similar to the standard light-sensitive vidicon that was utilized extensively in the commercial television industry. The XEBIT can replace an X-ray image intensifier coupled to a video camera using relay lenses with a single direct-conversion device [48.40]. The typical TlBr layer thickness is 300 μm .

The ionization energy $W_{\pm} \approx 6.5 \text{ eV}$ and the relative dielectric constant of TlBr is 33. The band-gap energy E_g of TlBr is 2.7 eV and its resistivity is $\approx 5\times 10^9 \Omega \text{ cm}$ under ambient conditions. At room temperature the dominant contribution to the dark current is ionic conductivity [48.40]. The ionic conductivity has an exponential dependence on temperature; the conductivity decreases by an order of magnitude for every 19 $^\circ\text{C}$ temperature decrease. Therefore, the dark current can be greatly decreased by Peltier cooling. $\mu_h\tau_h$ in TlBr is $\approx 1.5\times 10^{-6} \text{ cm}^2/\text{V}$ [48.40].

48.1.3 Summary and the Future

The material and imaging properties of potential photoconductors for X-ray image detectors are summarized in Tables 48.1 and 48.2. Stabilized a-Se is currently the best choice of photoconductor for clinical X-ray image detectors. The next closest competitor is the poly-HgI₂ imagers, which show excellent sensitivity, good resolution, and acceptable dark current, homogeneity and lag characteristics. However, the long-term stability of HgI₂ imagers has not been as thoroughly studied as

stabilized a-Se sensors. Both the dark current and the image-lag characteristics of CZT, PbI₂ and PbO detectors are worse than those of HgI₂ sensors. However, the X-ray detectors made with CZT photoconductive layers should be mechanically and chemically more stable than HgI₂-based detectors. The main drawback of a-Se detectors is its low conversion gain, which particularly affects the imaging sensor performance at low exposure. This can be overcome by utilizing the avalanche mul-

tiplication technique in the a-Se layer [48.41] and/or using on-pixel amplification [48.2]. However, further research is necessary to demonstrate basic operation as well as to examine the long-term stability of sensors utilizing these techniques. The main drawbacks of polycrystalline sensors are the image lag and the nonuniform response. Making smaller, finer and more uniform grain size in polycrystalline sensors may overcome these drawbacks.

48.2 Metrics of Detector Performance

X-ray sensitivity, resolution in terms of modulation transfer function (MTF), detective quantum efficiency (DQE), image lag and ghosting are often considered as the metrics of imaging performance. For most practical applications, the spatial-frequency-dependent (f -dependent) detective quantum efficiency, $DQE(f)$, is the appropriate metric of overall system performance and is unity at all f for an ideal detector. The detector performance depends critically on the photoconductor material properties such as the mobility, carrier trapping (both shallow and deep), EHP creation energy, X-ray attenuation and absorption coefficients. The material properties such as carrier mobility, EHP creation energy, X-ray attenuation and absorption coefficients in a well-defined photoconductor are almost constant, but the carrier lifetimes may vary from sample to sample. Shallow and deep trapping are particularly responsible for image lag and ghosting, respectively. The effects of charge-transport properties ($\mu\tau$) and the attenuation coefficient of photoconductor materials on the detector performance depends on L and F through the following normalized parameters,

$$\begin{aligned}\Delta &= \text{normalized attenuation depth} \\ & \quad (\text{attenuation depth/thickness}) \\ &= 1/(\alpha L), \\ x_e &= \text{normalized electron schubweg} \\ & \quad (\text{electron schubweg per unit thickness}) \\ &= \mu_e \tau_e F/L, \text{ and,} \\ x_h &= \text{normalized hole schubweg} \\ & \quad (\text{hole schubweg per unit thickness}) \\ &= \mu_h \tau_h F/L.\end{aligned}$$

where α is the linear attenuation coefficient of the photoconductor, $\mu_{e(h)}$ is the mobility and $\tau_{e(h)}$ is the deep-trapping time (lifetime) of electrons (holes).

Equivalently, x_e and x_h are the normalized carrier lifetimes (carrier lifetimes per unit transit time) for electrons and holes, respectively. The ranges of these normalized parameters for the three most promising photoconductive (a-Se, poly-HgI₂ and poly-CZT) X-ray image detectors are given in Table 48.3. The combined effects of charge-transport properties (mobility and carrier lifetime), operating conditions (F and E), photoconductor thickness, and the attenuation coefficient of the photoconductor material on the imaging characteristics (X-ray sensitivity, DQE, MTF and ghosting) are examined in the following sections. It must be emphasized that the photoconductor thickness L and the operating field F are as important to the overall performance of the detector as the material properties of the photoconductor itself, a point that will become apparent in the results presented in this chapter.

48.2.1 X-Ray Sensitivity

The X-ray sensitivity (S) of a photoconductive detector is defined as the collected charge per unit area per unit exposure of radiation and is considered an important performance measure for a superior image. High S permits the use of low detector radiation-exposure levels which also increases the dynamic range of the AMPFI. The selection of the X-ray photoconductor is highly influenced by the value of S .

The value of S can be considered to arise in terms of three controlling factors: firstly, the amount of radiation actually absorbed from the incident radiation that is useful for the generation of electron-hole pairs (EHPs), which is characterized by the quantum efficiency η of the detector and depends on the value of α of the photoconductor and L through $\eta = 1 - e^{-\alpha L}$, where the value of α is X-ray photon-energy-dependent; secondly, the generation of EHPs by X-ray interactions, which is char-

Table 48.3 The values of Δ , x_e and x_h for a-Se, poly-HgI₂ and poly-CZT detectors

Photoconductor	$\mu_e \tau_e$ (cm ² /V) $\mu_h \tau_h$ (cm ² /V)	F (V/ μ m)	E (keV)	L (mm)	x_e	x_h	Δ
Stabilized a-Se	$\mu_e \tau_e = 0.3 \times 10^{-6} - 10^{-5}$	≈ 10	20	0.2	1.5–50	5–300	0.24
	$\mu_h \tau_h = 10^{-6} - 6 \times 10^{-5}$		60	1.0	0.3–10	1–60	0.98
Poly-HgI ₂	$\mu_e \tau_e \approx 10^{-6} - 10^{-5}$	0.5–1	20	0.15	0.7–7	≈ 0.1	0.21
	$\mu_h \tau_h \approx 10^{-7}$		60	0.3	0.35–3.5	≈ 0.05	0.85
Poly-Cd _{0.95} Zn _{0.05} Te	$\mu_e \tau_e \approx 2 \times 10^{-4}$	≈ 0.25	20	0.3	≈ 17	≈ 0.25	0.26
	$\mu_h \tau_h \approx 3 \times 10^{-6}$		60	0.3	≈ 17	≈ 0.25	0.89

acterized by the value of W_{\pm} of the photoconductor and the average absorbed energy (E_{ab}) per attenuated X-ray photon of energy E , where W_{\pm} depends on the material properties of the photoconductor, and E_{ab} depends on the incident X-ray photon energy [48.42] and the material properties; and thirdly, how much of the X-ray generated charge is actually collected in the external circuit. This is characterized by the charge-carrier drift mobilities (μ) and lifetimes (τ), the applied F and L .

The S of an X-ray image detector can be normalized with respect to the maximum sensitivity (S_0) that would arise if all the incident radiation were absorbed and all the liberated carriers were collected. Neglecting secondary photon interactions, the expression for S_0 is [48.22]

$$S_0 = \left(\frac{5.45 \times 10^{13} e}{(\alpha_{air}/\rho_{air}) W_{\pm}} \right) \left(\frac{\alpha_{en}}{\alpha} \right), \quad (48.3)$$

where e is the elementary charge, α_{en} is the energy absorption coefficient of the photoconductor, while α_{air} and ρ_{air} are the energy absorption coefficient of air and its density. If W_{\pm} is expressed in eV, α_{air}/ρ_{air} is in cm²/g and exposure in (48.3) is in Roentgens, then S_0 is in units of C/cm²R. Thus S_0 is a constant that depends on E and the material properties of the photoconductor, since W_{\pm} is a material property which can usually be taken as constant for a given material. For those materials (e.g., a-Se) that have a significant F - and/or E -dependent W_{\pm} , then S_0 depends on F and/or E .

The quantity $s = S/S_0$ takes into account the X-ray absorption and charge-transport effects and is called the charge-collection and absorption-limited normalized sensitivity. It should be emphasized that s is a quantity that is determined by the X-ray absorption profile, photoconductor thickness and the charge-collection efficiency. The s of an X-ray image detector considering small signal operation, a constant μ and a single deep-trapping time (lifetime) τ for each type of carrier (holes and electrons) and neglecting carrier diffusion is given

by [48.43],

$$\begin{aligned} S/S_0 &= x_h \left[\left(1 - e^{-\frac{1}{\Delta}} \right) + \frac{1}{\Delta/x_h - 1} \left(e^{-\frac{1}{x_h}} - e^{-\frac{1}{\Delta}} \right) \right] \\ &\quad + x_e \left[\left(1 - e^{-\frac{1}{\Delta}} \right) - \frac{1}{\Delta/x_e + 1} \left(1 - e^{-\frac{1}{\Delta} - \frac{1}{x_e}} \right) \right] \\ &= s_h(x_h, \Delta) + s_e(x_e, \Delta) = s(x_h, x_e, \Delta) \end{aligned} \quad (48.4)$$

where subscripts h and e refer to holes and electrons respectively.

The two square brackets on the right-hand side of the normalized sensitivity s expression (48.4) represent the relative contributions of hole and electron transport to the overall sensitivity for a given Δ . It is assumed in (48.4) that the radiation receiving side of the detector is biased positively. If the bias polarity is reversed, then x_e and x_h must be interchanged. The expression in (48.4) applies for incident radiation that is monoenergetic and has to be appropriately integrated over the radiation spectrum of a practical polyenergetic X-ray source by considering the X-ray photon-energy-dependent terms W_{\pm} , α and α_{en} . Equation 48.4 applies to an isolated photoconductor sandwiched between two large-area parallel-plate electrodes (small pixel effects are excluded) [48.44] and operating under a constant E (small signal case). An excellent fit of (48.4) to experimental data on poly-HgI₂ is given in [48.30].

The value of s is always less than unity since S for a photoconductor of finite thickness in which carrier collection is not perfect is always less than S_0 . Note that $s(x_h, x_e, \Delta) = s_h + s_e = 1$ when all the incident radiation is absorbed and all the charges are collected, i.e., $x_h, x_e \gg 1$ and $\Delta \ll 1$. The sensitivity is then simply S_0 and is controlled by W_{\pm} .

The sensitivity is mainly controlled by the charges that have the same polarity as the bias on the radiation-receiving electrode: holes for positive bias and electrons for negative bias [48.30, 43]. The extent of the disparity between s_h and s_e depends on Δ . The disparity

Table 48.4 X-ray sensitivity of a-Se, poly-HgI₂ and poly-CZT detectors using the normalized parameters from Table 48.3

Photoconductor	E (keV)	S_0 ($\mu\text{C}/\text{cm}^2\text{R}$)	$s = S/S_0$		S ($\mu\text{C}/\text{cm}^2\text{R}$)	
			Positive bias	Negative bias	Positive bias	Negative bias
Stabilized a-Se	20	0.244	0.9–0.98	0.8–0.98	0.22–0.24	0.2–0.24
	60	5.37	0.39–0.64	0.35–0.62	2.1–3.38	1.88–3.35
Poly-HgI ₂	20	2.75	0.25–0.29	0.53–0.81	0.7–0.81	1.46–2.24
	60	38.54	0.15–0.3	0.21–0.4	6.76–11.21	8.18–15.6
Poly-Cd _{0.95} Zn _{0.05} Te	20	3	≈ 0.456	≈ 0.85	≈ 1.37	≈ 2.55
	60	35.87	≈ 0.41	≈ 0.51	≈ 14.69	≈ 18.12

is stronger for lower Δ , which can be understood by noting that electron and hole generation do not occur uniformly throughout the thickness of the sample but rather it is more effective closer to the radiation receiving electrode. An advantage of a-Se detectors is that both x_e and x_h are much greater than one, which is not the case for other photoconductors, as shown in Table 48.3. Therefore, charge collection in a-Se detectors is close to unity and the normalized sensitivity is controlled by the quantum efficiency of the detector. The S and s of different photoconductive detectors using the normalized parameters from Table 48.3 are given in Table 48.4. The values of W_{\pm} for a-Se were taken from the work of Blevis et al. [48.20]. At $F = 10 \text{ V}/\mu\text{m}$, $W_{\pm} = 42.5$ and 46 eV for X-ray photon energies of 60 and 20 keV, respectively. The maximum X-ray sensitivity S_0 of chest

radiographic detectors ($E = 60 \text{ eV}$) is much higher than of mammographic detectors ($E = 20 \text{ eV}$) because of the lower $\alpha_{\text{air}}/\rho_{\text{air}}$ values in (48.3) at higher X-ray photon energies [48.42]. The value of S_0 in a-Se detectors is much lower than in poly-HgI₂ and poly-CZT detectors because of the higher value of W_{\pm} in a-Se.

48.2.2 Detective Quantum Efficiency

DQE measures the ability of the detector to transfer signal relative to noise from its input to its output. The random nature of image quanta gives rise to random fluctuations in image signals, which contributes to image formation and hence creates random noises. The scattering of image quanta gives rise to image blurring, which is quantified by the $\text{MTF}(f)$. Images are partially degraded by various sources of statistical fluctuations that arise along the imaging chain. The relative increase in image noise due to an imaging system as a function of spatial frequency f is expressed quantitatively by $\text{DQE}(f)$ which represents the signal-to-noise transfer efficiency for different frequencies of information in an image. $\text{DQE}(f)$ is defined as

$$\text{DQE}(f) = \frac{\text{SNR}_{\text{out}}^2(f)}{\text{SNR}_{\text{in}}^2(f)}, \quad (48.5)$$

where SNR_{in} and SNR_{out} are the signal-to-noise ratios (SNR) at the input and output stages of the image detector, respectively. $\text{DQE}(f)$ is unity for an ideal detector. For simplicity, we are often interested in measuring $\text{DQE}(f = 0)$ of an imaging detector since it represents the signal quality degradation due to the signal and noise transfer characteristics of the system without considering signal spreading.

The random nature of charge-carrier trapping (i. e. incomplete charge collection) in the photoconductor layer creates fluctuations in the collected charge and hence creates additional noise. Thus carrier trapping degrades signal-to-noise performance of the image and reduces the DQE. Recently, Kabir and Kasap [48.45]

Fig. 48.7 $\text{DQE}(0)$ versus X-ray exposure for a-Se, poly-HgI₂, and poly-CZT detectors and for a 60-keV monoenergetic X-ray beam. The electronic noise is 2000 e per pixel. It is assumed that $F = 10 \text{ V}/\mu\text{m}$ for a-Se, $0.5 \text{ V}/\mu\text{m}$ for HgI₂ and $0.25 \text{ V}/\mu\text{m}$ for CZT

have examined the effects of charge-carrier trapping on the $DQE(0)$ of an a-Se detector by considering depth-dependent conversion gain and depth-dependent charge-collection efficiency in the cascaded-linear-system model [48.46, 47]. In this section, the $DQE(0)$ model of *Kabir and Kasap* [48.45] is applied to potential photoconductive detectors such as a-Se, poly-HgI₂ and poly-Cd_{0.95}Zn_{0.05}Te detectors for fluoroscopic applications to study and compare their $DQE(0)$ performance.

Figure 48.7 shows $DQE(0)$ as a function of X-ray exposure for a-Se, HgI₂, and CZT detectors for a 60-keV X-ray beam. The X-ray exposure (X) is varied from 0.1 μ R to 10 μ R, which is the range of X-ray exposure for fluoroscopic applications. We assume that the pixel area, $A = 200 \mu\text{m} \times 200 \mu\text{m}$, and the effective fill factor is 1.0 for all types of photoconductors. The average E is 60 keV and the additive electronic noise (N_e) is assumed to be 2000 electrons per pixel. The following transport and operating parameters are used in Fig. 48.7: for a-Se detectors, $L = 1000 \mu\text{m}$, $F = 10 \text{ V}/\mu\text{m}$, $W_{\pm} \approx 43 \text{ eV}$, $\mu_e \tau_e = 10^{-6} \text{ cm}^2/\text{V}$ and $\mu_h \tau_h = 10^{-5} \text{ cm}^2/\text{V}$; for HgI₂ detectors, $L = 260 \mu\text{m}$, $F = 0.5 \text{ V}/\mu\text{m}$, $W_{\pm} = 5 \text{ eV}$, $\mu_e \tau_e = 6 \times 10^{-6} \text{ cm}^2/\text{V}$ and $\mu_h \tau_h = 10^{-7} \text{ cm}^2/\text{V}$; and for CZT detectors, $L = 270 \mu\text{m}$, $F = 0.25 \text{ V}/\mu\text{m}$, $W_{\pm} = 5 \text{ eV}$, $\mu_e \tau_e = 2 \times 10^{-4} \text{ cm}^2/\text{V}$ and $\mu_h \tau_h = 3 \times 10^{-6} \text{ cm}^2/\text{V}$. The radiation-receiving electrode is biased positively for a-Se detectors and negatively for HgI₂ and CZT detectors. $\Delta \approx 0.98$ is for all photoconductors. $\eta = 1 - \exp(-1/\Delta) \approx 0.64$ is the maximum achievable $DQE(0)$ if all the liberated charges are collected.

The DQE for the CZT detector is relatively unchanged over the whole exposure range due to a large conversion gain (low W_{\pm}) and high charge-collection efficiency (good transport properties). The DQE for a-Se detectors is small at low exposures because of its relatively low conversion gain and is controlled by the added electronic noise. As the X-ray exposure increases, each pixel receives more photons. The relative contribution of electronic noise to the total noise becomes less important and the DQE increases. The DQE for HgI₂ detectors is relatively small even at higher exposures because of its low charge-collection efficiency, which gives rise to considerable gain-fluctuation noise. Therefore, both high conversion gain and high charge-collection efficiency are required to improve the DQE performance of an X-ray image detector [48.48]. The conversion gain depends on W_{\pm} , which is a material property of the photoconductor. The charge-collection efficiency can be improved by increasing F and improving the $\mu\tau$ products of the carriers. However, increasing

F also increases the dark current dramatically in both HgI₂ and CdZnTe detectors. Thus there is a practical limitation on F . An F as high as $20 \text{ V}/\mu\text{m}$ is achievable in a-Se detectors while keeping the dark current within an acceptable level for X-ray imaging [48.26]. The charge-collection efficiency of a-Se detectors is relatively high because of the high F needed to obtain a reasonable W_{\pm} .

48.2.3 Modulation Transfer Function (MTF)

Resolution or resolving power is the ability to record separate images of small objects that are placed very closely together. The overall resolution of a system can be expressed as a convolution of the component resolutions. However, the spatial resolution of an imaging device or a system can also be described in terms of the MTF , which is the relative response of the system as a function of spatial frequency. The MTF of an imaging system can be described as a cascade of several stages where the overall MTF is simply the product of the $MTFs$ of all the individual stages. The $MTF(f)$ is a much more convenient descriptor of spatial response since the resolving power from multiplication is much more easily comprehended than convolution. The overall MTF (or presampling MTF) of an image detector can be expressed as,

$$MTF(f) = MTF_m(f) \times MTF_a(f), \quad (48.6)$$

where $MTF_m(f)$ is the modulation transfer function of the detector material and $MTF_a(f)$ is the modulation transfer function associated with the aperture function of the pixel electrodes. $MTF_a(f)$ arises due to averaging of the signal over a pixel area. If the aperture is square with dimension a , then, $MTF_a(f)$ will be of the form $\text{sinc}(af)$. The aperture MTF describes how spatial frequencies are passed through the detector elements.

The spatial resolution in direct-conversion AMFPI is high and closer to the aperture function, as compared to phosphor-based AMFPI. Based on current understanding, charge-carrier trapping and reabsorption of K-fluorescent X-ray photons are the two dominant mechanisms responsible for the loss of resolution [48.48] in direct-conversion AMFPI. Some of the K-fluorescent X-ray photons may be reabsorbed at different points within the detector volume from the primary X-ray-photon interaction point. This creates a lateral spreading of signal and a loss of resolution. The loss of resolution due to fluorescence reabsorption is maximum (although not very substantial [48.48]) just above the K-edge of the photoconductor. This effect can

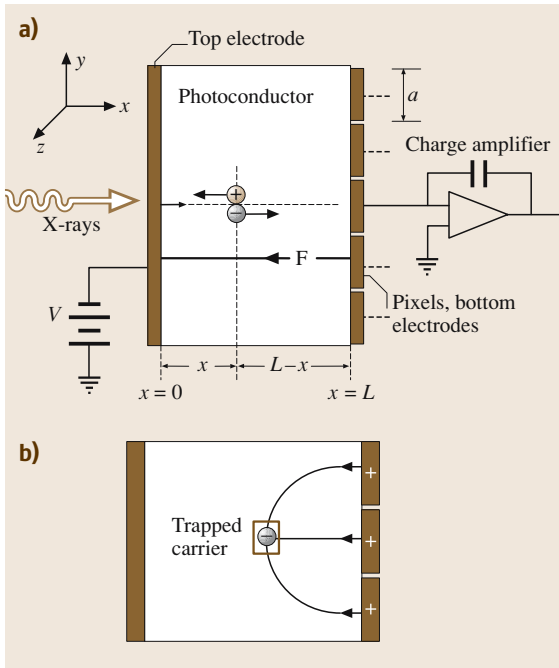

Fig. 48.8 (a) A cross section of a direct-conversion pixelated X-ray image detector. (b) Trapped carriers in the photoconductor induce charges not only on the central pixel electrode but also on neighboring pixel electrodes, spreading the information and hence reducing spatial resolution

be ignored when: (i) the incident X-ray photon energy is lower than the K-edge of the photoconductor, or (ii) the mean energy of the X-ray beam and the K-edge occur at widely different energies [48.49]. The charge-carrier trapping has a significant effect on the resolution of these direct-conversion X-ray image detectors [48.36], which will be discussed below.

The direct-conversion AMFPI geometry consists of a photoconductor layer sandwiched between two electrodes; the electrode at one side is a continuous metal plate and the electrode on the other side of the photoconductor is segmented into an array of individual square pixels of size $a \times a$, as shown in Fig. 48.8a. The geometric pixel aperture width in a flat-panel detector is smaller than the pixel pitch (center-to-center spacing between two pixels). However, it has been shown that the effective fill factor (the effective fraction of pixel area used for image-charge collection) of a photoconductive flat-panel detector is close to unity [48.28, 51]. Therefore, the effective pixel aperture width a is virtually identical to the pixel pitch. Some of the X-ray-generated carriers are captured by deep traps in the bulk of the photo-

Fig. 48.9 Measured presampling MTF of a polycrystalline CdZnTe detector in comparison with modeled results that included blurring due to charge-carrier trapping in the bulk of the photoconductor. The detector thickness is 300 μm and the pixel pitch is 150 μm . (after Fig. 10 of [48.50])

conductor during their drift across the photoconductor layer. Suppose that a carrier is trapped in the photoconductor above a particular (central) pixel electrode of a pixelated image sensor. This trapped carrier induces charges not only on the central pixel electrode but also on neighboring pixel electrodes, as shown in Fig. 48.8b, and consequently there is a lateral spread of information and hence a loss of image resolution.

Kabir and Kasap [48.36] have developed an analytical expression for the MTF due to distributed carrier trapping in the bulk of the photoconductor and examined the effect of charge-carrier trapping on the resolution of direct-conversion AMFPI. The effect of trapping on MTF increases with decreasing normalized carrier lifetime (i.e., normalized schubweg). Trapping of the carriers that move towards the pixel electrodes degrades the MTF performance, whereas trapping of the other type of carriers, which move away from the pixels, improves the sharpness of the X-ray image.

Figure 48.9 shows the experimental MTF and theoretical fit of a 300- μm -thick positively biased CZT detector exposed to an 80-kVp X-ray beam with 26-mm Al filtration. The experimental data have been extracted from Fig. 10 of [48.50]. The operating $F = 0.25 \text{ V}/\mu\text{m}$ and pixel pitch is 150 μm . The Nyquist frequency is 3.3 lp/mm. The dotted line shows the MTF due to the bulk carrier trapping only. The bulk carrier trapping has a significant effect on the

MTF of the detector. As is apparent from Fig. 48.9, there is very good agreement between the model and the experimental data. The best-fit $\mu\tau$ products of electrons and holes $\mu_e\tau_e = 2.4 \times 10^{-4} \text{ cm}^2/\text{V}$ and $\mu_h\tau_h = 3.2 \times 10^{-6} \text{ cm}^2/\text{V}$, which are very close to the

$\mu\tau$ values reported previously [48.32, 35]. Although the charge-carrier-trapping-limited MTF model has been applied to the CZT sensors, the model can also be applied to other photoconductive (e.g., a-Se and HgI₂) panel X-ray image detectors.

48.3 Conclusion

The principles of operation of a direct-conversion AMFPI for medical applications have been briefly discussed. The charge-transport and imaging properties of some of the potential photoconductors have been critically discussed and compared with the properties of an ideal photoconductor for X-ray image detectors. The various imaging characteristics of photoconductor-based AMFPIs such as the sensitivity (*S*), detective quantum efficiency (DQE), and resolution in terms of the modulation transfer function (MTF) have also been examined. These characteristics depend critically not only on the photoconductor's charge-transport properties but also on the detector structure, i.e., the size of the pixel and the thickness of the photoconductor. It has been shown that the detector structure in terms

of the photoconductor thickness and the pixel size is just as important to the overall performance of the detector as the material properties of the photoconductor itself.

Recent experiments on a-Se detectors indicate that the X-ray-sensitivity of this detector decreases in subsequent exposures. The study of ghosting mechanisms in a-Se-based AMFPI is currently considered as an active research area since the origins of ghosting have not been fully resolved [48.52]. We expect that the ghosting phenomenon may also be present in other photoconductive (e.g., HgI₂, CZT, PbO and PbI₂) detectors, although it has not yet been measured. Long-term stability, and X-ray-induced effects and phenomena are also current research topics.

49. Phase-Change Optical Recording

The present chapter takes the reader from the basics of phase-change recording up to the latest achievements in the field. It discusses in detail the specific features of Te-based compounds that made them the best materials for phase-change data storage. It is demonstrated that the essence of phase-change recording does not consist of simple disordering of the medium through melting and subsequent quenching as previously believed but is due to a switch of Ge atoms between octahedral and tetrahedral symmetry positions within the Te face-centered cubic lattice. It is this nature of the transition that makes the Te-based media fast and stable. The chapter is concluded by the introduction of a concept of the super-resolution

near-field structure (super-RENS) disc that allows the reduction of the bit size well below the diffraction limit and makes 100 GB/disc storage a reality.

The idea of phase-change recording dates back to the mid 1960s when *Ovshinsky* [49.1] first suggested using differences in electrical and optical properties between amorphous and crystalline phases of Te-based chalcogenides for data storage. The idea of phase-change recording is quite simple.

When a melt is cooled down slowly, such that the structure always remains in thermal equilibrium, upon

reaching the crystallization temperature the material crystallizes, i. e. is transformed into a solid state with a well-defined periodic structure. If, on the other hand, the cooling rate is fast, then at a certain temperature the viscosity of the liquid increases to a degree such that the structure can no longer relax following the changes in temperature; one obtains a supercooled liquid and then a glass. In contrast to the crystallization temperature, the glass-transition temperature is not well defined. A range of temperatures exist and the particular temperature of the glass transition depends on the cooling rate.

Once in the solid state, the glass, if kept at a temperature close to the glass-transition temperature, crystallizes. On the other hand, rapid heating of the crystalline material to a temperature above the melting point and subsequent rapid cooling (quenching) can produce a glassy state. This glass-formation diagram is demonstrated by Fig. 49.1.

The material can also be heated by light. Exposure of an amorphous material to a laser light that heats it above the glass-transition temperature results in crystallization while short and intense laser pulses melt the material and—provided the heat-dissipation rate is fast enough—an amorphous recorded bit is formed.

Fig. 49.1 A glass-formation diagram

49.1 Digital Versatile Discs (DVDs)

The latest commercial implementation of phase-change recording are rewritable digital versatile disks (DVDs) [49.2]. Various materials have been tried for potential use in phase-change memories and the best in terms of speed and stability are ternary Ge–Sb–Te (primarily $\text{Ge}_2\text{Sb}_2\text{Te}_5$, hereafter referred to as GST) and quaternary Ag–In–Sb–Te (AIST) alloys. The former are used in DVD random access memory (DVD-RAM) and the latter in DVD rewritable (DVD-RW) disks. While there are some differences in the device structure and recording strategies, both these kinds of rewritable DVDs are capable of storing up to 4.7 Gbits of information.

A basic disk structure consists of four layers (Fig. 49.2). The recording layer (GST or AIST) is sandwiched between Zn–SiO₂ layers and a metallic Al–Cr layer serves as a reflection layer and also as a heat sink to ensure the rapid cooling necessary for the formation of the amorphous phase.

49.1.1 Questions Pertaining to DVD Recording

While the phenomenology of phase-change recording is simple, the realistic nanoscale mechanism of the structural transformation has remained unclear for almost 30 years since the idea of phase-change recording was first suggested.

In particular, there are several fundamental questions that need to be answered. Interestingly, some of them have never been asked previously.

1. If the process consists of simple crystallization and melting there should be a wide variety of suitable composition. Why are GST and AIST the best materials?
2. Commercial DVD-RAM is stable for over 1 000 000 cycles. What makes the switching so reproducible and the media so stable?
3. GST crystallizes within 30 ns and amorphous bits can be recorded with femtosecond pulses. Why are the structural transformations so fast? Structure relaxation involving ordering of the amorphous material is likely to proceed on a longer time scale.
4. The crystallization process is characterized by an activation energy of 2–3 eV. Should the crystallization be a solid-state process, one would expect the activation energy to be on the order of the energy gap, i. e. ≈ 0.3 eV. The observed activation energy is rather

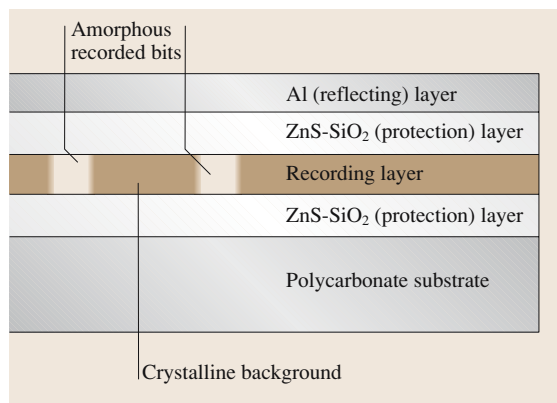

Fig. 49.2 A schematic representation of a DVD structure

reminiscent of a molecular-type excitation. Why is the activation energy so high?

5. In typical semiconductors (and in chalcogenides in particular), the amorphous phase is characterized by a smaller band gap than the crystalline phase. This is typically due to the fact that the bonds in the amorphous materials are weaker and hence the splitting between the bonding and antibonding states, which form the valence and conduction bands, respectively, is smaller. In phase-change materials the situation is reversed, namely, it is the crystalline phase that possesses a narrower band gap and higher reflectivity than the amorphous phase. What is the reason for this abnormality?
6. And, finally, what is the role of light? Although it has been tacitly assumed that light is simply heating the material, a very high concentration of nonequilibrium carriers created by intense light may—and most likely does—play a role.

In order to develop novel optical media insightfully, one has to answer the above questions. These, in turn, require detailed knowledge of the structure of the material in both the crystalline and amorphous phases as well as the atomic mechanism of the structural changes upon the phase transition.

49.1.2 Local Structure and its Changes During the Phase Transition

An ideal tool to investigate the local structure of a material and its changes on the atomic scale independent of the state of the material (crystalline or

amorphous) is X-ray absorption fine-structure (XAFS) spectroscopy.

Extended X-ray absorption fine structure (EXAFS) allows one to obtain information about the local structure around selected chemical species, such as the average coordination number, the bond lengths, the chemical nature of the neighboring species, as well as the bond-length disorder parameter, or mean-square relative displacement (MSRD). The technique is selective to the absorbing atom, which allows one to probe the local structure around different constituent elements independently.

X-ray absorption near-edge structure (XANES), which involves multiple scattering, additionally allows one to probe the local arrangement of atoms on a scale somewhat beyond the first-nearest neighbors, in particular, it is sensitive to the mutual arrangement of the neighboring atoms in space, i.e. includes bond-angle information. As XANES features are also a consequence of transitions from occupied core states to unoccupied conduction-band states, the spectra also contain information about the density of unoccupied conduction-band states. It should be mentioned that recent advances in theory have made it possible to simulate EXAFS and XANES spectra with good accuracy [49.3].

The Crystalline State

The stable crystal structure of GST is hexagonal [49.4,5]. Thin films, however, crystallize into a different structure. Recent X-ray diffraction (XRD) studies have lead to a conclusion that thin GST layers crystallize into the rock-salt structure with Te atoms oc-

Fig. 49.3 Structure of metastable crystalline Ge–Sb–Te as suggested based on X-ray diffraction measurements

cupying sites on one face-centered cubic (fcc) sublattice with Ge and Sb randomly forming the other fcc sublattice (20% of the sites being vacant) (Fig. 49.3) [49.6, 7]. A lattice parameter of 6.02 Å was reported. The isotropic atomic displacements B_0 , which is a measure of atomic displacements from the ideal crystallographic positions due e.g. to thermal vibrations, found via the fitting process were 1.2 Å² and 3.2 Å² for the Te, and Ge(Sb) species, respectively, which correspond to atomic displacements of 0.1 Å and 0.2 Å for the Te and Ge(Sb) species, respectively.

It was suggested [49.5] that the cubic structure of GST (which is rather isotropic and hence more similar to the amorphous structure than any other crystal structure)

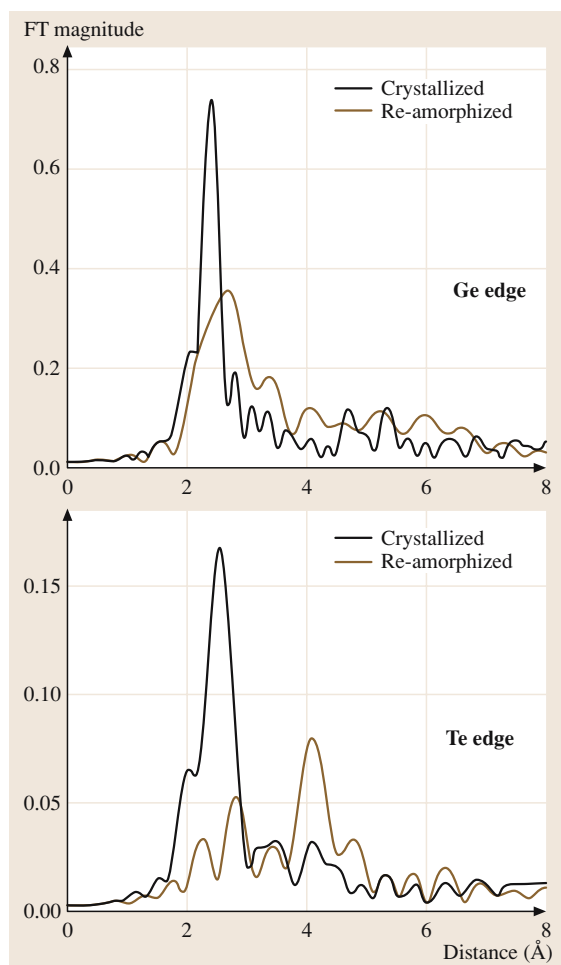

Fig. 49.4 Fourier-transformed Ge and Te K-edge EXAFS spectra of Ge₂Sb₂Te₅ measured for both the crystalline and amorphous states

was the reason for the high-speed switching and stable performance.

The above result gives rise to one more question. Why is B_0 so large (7% of the bond length)? In other words, is the structure really rock salt?

Below we summarize the authors' recent efforts to investigate the local structure of GST using XAFS. Measurements were performed at BL12C at the Photon Factory (Tsukuba, Japan) and BL01B1 at SPring8 (Hyogo-ken, Japan).

The Fourier-transformed (FT) spectra for the Ge and Te edges of GST are shown in Fig. 49.4. It should be noted that the r -space data shown in Fig. 49.4 are not real-space radial distribution function data but the magnitude of the Fourier transforms (FTs) of the k -space EXAFS data. The peak positions in the figure are shifted from the actual interatomic distances toward lower r because of the photoelectron phase shift $\delta(k)$ in the phase factor of the EXAFS oscillations. The spectra measured at the Sb edge did not show any significant variation between the two states and are not shown here.

Details of the data analysis can be found elsewhere [49.8]. The main results for crystalline GST are summarized below. We found two types of bond lengths, namely shorter bonds and longer bonds for both Te–Ge and Te–Sb (for Te–Ge: 2.83 ± 0.01 Å, and 3.2 ± 0.3 Å and for Te–Sb: 2.91 ± 0.01 Å and 3.2 ± 0.3 Å). It should be noted here that the observation of splitting of the bond lengths into two groups is very similar to the case of GeTe. The uncertainties for the longer bonds are rather large. For this reason no definitive conclusions could be drawn about the longer bonds and in what follows we shall exclusively concentrate on the shorter bonds. It should be noticed here that another commercially used material, AIST, also possesses subsets of shorter and longer bonds [49.9].

No Sb–Ge bonds were detected, in agreement with the fact that Sb and Ge do not intermix in the solid phase but we clearly observed a second-nearest-neighbor Te–Te peak at 4.26 Å.

It should also be mentioned that the mean-square relative displacements (MSRD) of the Te–Ge bond length obtained in EXAFS are considerably (lower (0.02 Å²) than) the isotropic atomic displacements of single atoms obtained from XRD (0.04 Å²). This result demonstrates that Ge and Sb atoms do not deviate from the ideal rock-salt positions in a random way but in a strongly correlated manner with respect to the neighboring Te atoms, i.e. the crystalline structure is in fact a *distorted* rock-salt-like structure similar to the case of the ferroelectric GeTe. The off-center location of the Ge atoms

Fig. 49.5 Structural modification of GST upon transformation from the crystalline (*left*) to amorphous (*right*) state (after [49.8])

means that there is a net dipole moment and suggests that GST is a ferroelectric material [49.10].

The Amorphous State

We now turn to the amorphous state. It was found that both Te–Ge and Te–Sb bonds get *shorter* (2.61 Å and 2.85 Å, respectively) and *stronger* upon amorphization, as evidenced by Fig. 49.4. At the same time, the Te second-neighbor peak becomes considerably weaker but does not disappear completely. The MSRD value decreases from 0.02 Å² in the crystalline state to 0.008 Å² in the amorphous state.

Such a behavior is highly unusual for typical three-dimensional covalently bonded solids as, due to the anharmonicity of interatomic potentials, disordering typically results in an increase of the bond lengths and the bond-length disorder. The obtained results reminds one of the case of molecular solids where the presence of intermolecular and intramolecular bonds determines the crystallization–amorphization behavior.

In the current case, a bond-strength hierarchy also exists and the following model of structural rearrangement can be envisaged. Upon melting, the longer Te–Ge (and Te–Sb bonds) are broken and, as a result, the shorter bonds become even shorter and stronger, i.e. the amorphous phase is *locally* more ordered than the crystalline phase. Our Raman scattering experiments provided further grounds for this model, namely, the Raman measurements for both GeTe and GST [49.11] showed that the spectra for the crystalline films are dominated by a peak located at lower wavenumbers, i.e. “mode softening” takes place upon crystallization. This situation can be compared with the case of Se or Te when the interchain interaction is weakened, giving rise to a Raman peak located at higher wave number [49.12]. It should be mentioned that an increased local bond or-

der in the amorphous phase was also observed for selenium [49.13].

To get further insight into the structure of the amorphous phase, we also performed XANES simulations and found that the best agreement with experiment was obtained when Ge was allowed to acquire its preferred tetrahedral surrounding in the amorphous phase [49.8, 11].

This structural transformation is illustrated in Fig. 49.5 where a Ge atom is shown within the fcc sublattice formed by Te atoms. The Ge atoms occupy octahedral and tetrahedral symmetry positions in the crystalline and amorphous states, respectively. The stronger covalent bonds are shown with thicker lines than the weaker bonds (Fig. 49.5 left). An intense laser pulse induces rupture of the weaker bonds and the Ge atom flips into the tetrahedral position (Fig. 49.5 right). An alternative description of the structural transformation upon melting is an umbrella-flip distortion resulting in disordering of the Ge sublattice. Notice, that the three covalent bonds remain intact. This conservation of the system of stronger covalent bonds is crucial: the material is not molten in a conventional sense.

Support for the aforementioned transformation comes from an estimate of the Ge–Te distance from the crystallographic data. Using a lattice parameter of GST obtained by X-ray diffraction [49.6, 7]), the Ge–Te distance—the Ge atoms being in a tetrahedral symmetry position—can be easily calculated to be 2.61 Å, i. e. exactly the value obtained from the EXAFS analysis. This consistency between the results obtained using two different structural techniques is the ultimate proof of the suggested structural modification as well as the generality of the structural modification in GeTe-based alloys.

It is interesting to note that very similar bond lengths for the crystalline and amorphous states were also observed for the binary GeTe [49.11, 14, 15], indicating that it is the GeTe component of the quasibinary

GeTe–Sb₂Te₃ that is mainly responsible for the observed phase transition.

Sb-edge XANES does not exhibit any significant changes upon amorphization (except for the Sb–Te bond shortening [49.8]) implying that the local arrangement of atoms around Sb remains essentially unchanged in accordance with the above model. We believe that the Sb atoms mainly play the role of enhancing overall stability of the metastable crystal structure by participating in the overall electron balance.

Intermediate-Range-Order Changes

The structural change on an *intermediate-range-order* scale can be viewed as following (Fig. 49.6). After rupture of the weaker Ge–Te bonds the Ge atoms flip into the tetrahedral symmetry position forming the GeTe₄ tetrahedra. At the same time, the broken weaker Ge–Te bonds no longer counterbalance the Sb–Te bonds on the opposite site and, as a result, the Sb–Te bonds become structure-determining. The structure relaxes making the Sb–Te bonds shorter (just as in amorphous Se the intrachain bonds get shorter upon amorphization [49.13]). The Sb–Te bond shortening upon amorphization has indeed been observed experimentally [49.8]. This can be viewed as the local phase separation into GeTe and Sb₂Te₃ phases. Finally, the structure relaxation causes a distortion in the Te fcc sublattice. It is important that the amorphous phase possesses a well-defined (single-state) structure without long-range periodicity. We believe that the well-defined local structure of the amorphous state is the reason for the overall stability of the GST-based optical media.

49.1.3 Related Issues

Although it is generally assumed that the role of a laser pulse is simply to heat the material, we believe that electronic excitation creating nonequilibrium charge carriers is crucial for the weakening and subsequent rupture of the subsystem of weaker Ge–Te bonds. Indeed, the presence of longer (weaker) bonds implies that the density of states corresponding to these bonds is lower in energy and hence photogenerated nonequilibrium carriers more readily populate these states, making them more susceptible to thermal vibration-induced dissociation.

As mentioned above, another commercially used material, AIST, has a similar bond hierarchy [49.9], which allows us to suggest that the basic mechanism underlying the phase-change transition in the two groups of materials are essentially the same.

Fig. 49.6 Medium-range-order changes in GST upon crystallization–amorphization transition

It should be stressed that this structural transformation involves a change in the hybridization from p-type bonding in the rock salt to sp^3 hybridization in the amorphous state. This substantial change in the electronic states accounts for the very large change in optical and electrical properties of GST upon the crystallization–amorphization transition.

It should also be noticed here that the unveiled structural modification can also account for why it is the crystalline regions that possess a smaller gap and higher reflectance. Indeed, the crystal structure involves both

shorter and longer bonds. The longer (and hence weaker) bonds are characterized by a smaller energy splitting between the bonding and antibonding states and thus determine the positions of the valence and conduction band edges (and the width of the band gap) in the crystal. In the amorphous phase, on the other hand, the initially weaker bonds break and disappear altogether and the initially stronger bonds get even shorter and stronger. As a result, the splitting between the bonding and antibonding states increases, which produces a larger band gap and lower reflectivity compared to the crystalline phase.

49.2 Super-RENS Discs

Recent progress in multimedia requires continuously higher storage densities and faster data access. A fundamental obstacle here is the so-called diffraction limit, which does not allow one to focus the beam into a spot smaller than $\Phi > \lambda/(2NA)$, where Φ , λ , and NA are the laser spot diameter, light wavelength and numerical aperture (< 1.0) of the lens, respectively.

Various approaches to tackle the problem have been suggested. The most promising among them (within optical data-storage limits) are the following: use of dual-layer disks, use of blue and blue–violet lasers (with a shorter wavelength), use of large numerical apertures, and use of the near-field technique. The latter technique allows one to avoid completely the restrictions on the dot size imposed by the diffraction.

Near-field recording is now being actively developed, following a different routes. One such route is the use of so-called super-resolution near-field structures (super-RENS) [49.16], recently developed at our center. The most important feature of this approach is that the near-field aperture is incorporated into the disk itself, i. e. the near-field recording is realized based solely on thin-film technology. Typical super-RENS structures are shown in Fig. 49.7.

As can be seen from the figure, in addition to the recording layer sandwiched between two capping layers there is a masking layer present. At the initial stages of super-RENS development the masking layer used was Sb (Fig. 49.7a). When an intense laser pulse hits the structure, the Sb layer heats up. When heated, the Sb undergoes the Peierls transition, i. e. a gap in the density of states is formed. As a result, a small aperture opens in it, which serves as a near-field light source [49.16]. The distance between the light source and the recording media is now fixed and determined by the thickness of the capping layer between the masking layer and the GST layer. With optimized parameters for each layer, the aperture in the Sb layer opens for sufficient time to record a bit into the GST layer. When the disk rotates and the exposed Sb spot moves away from the light, the aperture closes. A similar process takes place during the read-out stage.

Fig. 49.7 A schematic presentation of (a) transmission- and (b) scattering-type super-RENS discs

An alternative design contains a MeO_x ($\text{Me}=\text{Ag}$, Pt) as the masking layer. Light that is absorbed by the recording layer generates heat and thus causes decomposition of MeO_x with the subsequent formation of Me nanoparticles within an oxygen bubble (Fig. 49.7b) [49.17]. The role of the localized plasmons excited in the nanoparticles has been discussed in detail previously [49.18]. In what follows we very briefly discuss the role of the recording layer.

There are various questions regarding the write-in and read-out mechanisms of super-RENS. In particular, an important question is how can a laser beam with a diameter of $\approx 1\ \mu\text{m}$ read out individual bits with sizes on the order of 100 nm? While there is no definite answer to this question several alternatives have been suggested. Below we describe one possibility, viz., a model based on the ferroelectric catastrophe [49.10].

As discussed earlier, GST in its metastable crystalline form possesses a net dipole moment, i.e. it is a potential ferroelectric. Ferroelectrics are known to possess a very high dielectric constant in a rather narrow temperature range close to the Curie temperature. Intense light acting upon the disk during the read-out heats the rotating disk. Because of the rotation, the temperature profile is asymmetric. There is only a rather

Fig. 49.8 The ferroelectric catastrophe model of super-RENS read-out

narrow region where the temperature of the GST corresponds to the Curie temperature. It is only this region that possesses a high dielectric constant and a very high reflectivity, which enables one to read out marks whose size is considerably smaller than the laser spot [49.10].

Interestingly, the other phase-change material, AIST, is also one of the best materials for use in super-RENS discs. Since both kinds of materials possess longer and shorter bonds, and hence a net dipole moment, the suggested ferroelectric-catastrophe model may operate in both cases. Experiments to further investigate the ferroelectric properties of GST and AIST and their relevance to the super-RENS read-out mechanism are currently underway.

49.3 In Lieu of Conclusion

While it took almost 40 years to elucidate the origin of the structural change behind conventional phase-change recording, we hope that progress related to understanding of the super-RENS mechanism will be achieved on a much shorter timescale. To complete this chapter, we would like to note that presently

marks as small as 80 nm can be successfully recorded with a carrier-to-noise ratio (CNR) over 40 dB. The progress obtained in the field so far makes us confident that optical recording at a density higher than 100 GB/disc will become widely available in the very near future.

50. Carbon Nanotubes and Bucky Materials

The chapter details the underlying phenomena that underpin electronic applications that have followed from the discoveries of C_{60} and carbon nanotubes. The reduced dimensionality of these self-organised structures, high electron mobility, weak electromigration, and the plethora of quantum electronic effects exhibited by these structures suggest they are serious candidates for molecular electronics. The detail of the surface chemistry and conditions of synthesis assume greater importance than for conventional electronic materials since all atoms are on the exterior of these structures, as is outlined with references to the wider literature. Essential electronic structure information is given with reference to the transport measurements that have contributed greatly to the evolution of

the field with emphasis on the Coulomb blockade and ballistic transport phenomena. The major electronic applications are then outlined, giving the state-of-the-art figures of merit for performance and comments on prospects for realisation.

The discovery of C_{60} (Fig. 50.1) in 1986, and subsequently higher fullerenes, followed by that of carbon nanotubes in 1991 accelerated the interest in carbon-based molecules and compounds as electronically or optically active materials that had begun in the early

1970s. The emergence of the interdisciplinary field of nanotechnology has beneficially attracted attention and methodologies from other fields of science and engineering that have considerably enhanced the physical electronics research effort [50.1, 2].

50.1 Carbon Nanotubes

50.1.1 General

The electronic and structural description of carbon nanotubes and other sp^2 -bonded carbon nanostructures with curved surfaces (bucky materials, the term ‘bucky’ is derived from buckminsterfullerene: the name given to C_{60} soon after discovery) will inevitably contain references to that of the familiar two-dimensional (2-D) planar counterpart, graphite. The strength of the in-plane covalent bond of the hexagonal graphitic network produces a short C–C distance of 0.142 nm and high mechanical stiffness.

Carbon nanotube is a generic term that includes both single- and multi-walled structures. Single-wall carbon

Fig. 50.1 The C_{60} molecule, diameter 0.7 nm

Fig. 50.2 Single-wall carbon nanotube, length 1–10 μm , diameter typically 1.4 nm to > 10 nm

nanotubes (SWNTs) are seamless cylindrical graphitic macromolecules of nanoscale diameter and micrometer length, capped by hemispherical ends. The closure of the cylinder is a result of pentagonal inclusions in the hexagonal carbon network of the nanotube walls, Fig. 50.2. For SWNTs, every carbon atom is a surface atom. The smallest SWNT diameter reported to date, 4 Å, corresponds to the predicted lower limit for stable SWNT formation from consideration of the stress energy built into the cylindrical structure [50.3]. SWNTs tend to form closely packed bundles, or *ropes*, of several tens of individual single-wall nanotubes.

Multi-wall nanotubes (MWNTs) comprise several to tens of concentric cylinders of these graphitic shells with a layer spacing of 3.4 Å (the inter-planer spacing of graphite). SWNT diameters are typically ≈ 1 nm and a MWNT diameter can be in the range 2–100 nm with typical values of 10–20 nm. Nanotube lengths are typically 1–10 μm but can be ≈ 1 mm, giving rise to astonishing aspect ratios (length/diameter) of > 1000 . MWNTs of similar dimensions can also be formed from a single graphite sheet rolled into a scroll structure [50.4]. Double-wall carbon nanotubes are a recent addition to the set of carbon nanostructures.

A consequence of the high C–C bond strength is that the in-plane Young's modulus of a carbon nanotube is $\cong 1$ TPa, making the carbon nanotube one of the stiffest known materials, while the tensile strength is $\cong 150$ GPa (nanotubes have 600 times the strength/weight ratio of steel). Nanotubes deform elastically by buckling, have very low defect density over hundreds to thousands of interatomic spacings, and the strain energy built into the cylindrical structure tends to promote self-repair. The stiff nanotube structure means that the optical-phonon population is minimal even at room temperature; the result can be ballistic electron transport over micrometer length scales (several orders of magnitude greater than that in conventional semiconductor nanostructures).

Another consequence of the short C–C distance is spatially extensive overlapping hybridised atomic orbitals – a π -electron system – with highly mobile delocalised electrons on the interior and exterior of the structure. One carbon atom contributes one unpaired π -electron to the nanotube. The promise of very high carrier mobility in the π -electron system is one motivation for carbon-based electronics. Another is the range of electronic attributes that are displayed by the carbon allotropes, e.g. room-temperature resistivity can range from $10^{-8} \Omega\text{m}$ for SWNTs to $> 10^{18} \Omega\text{m}$ for crystalline C_{60} .

The π -electron system and stiff structure produce electrical conductivity, very high current-carrying capacity with weak electromigration. The best figures of merit for nanotube systems that have been measured since discovery are: electrical conductivity, $10^8 \Omega^{-1}\text{m}^{-1}$ (comparable with that of copper), carrier mobility: $10^4 \text{cm}^2/\text{Vs}$ (comparable with that of high-quality GaAs), thermal conductivity 10^4W/mK (comparable with that of diamond), and sustainable current density of 10^{13}A/m^2 (> 1000 times greater than that of a metal nanowire).

Nanotube circumferential crystal momentum vectors are quantised due to the periodic boundary conditions imposed by the finite nanoscale diameter whereas those directed along the micrometer-scale axis show continuous variation; thus, one-dimensional (1-D) electronic transport is intrinsic for the SWNT. Electronic systems of reduced dimensionality – dots, wires and sheets of charge – created by top-down silicon processing have assumed importance in conventional microelectronics. Carbon nanostructures offer the possibility of self-organised molecular-level low-dimensional electronic systems, e.g.: zero-dimensional (0-D) (C_{60} and short SWNTs), 1-D (SWNTs), 2-D (large-diameter MWNT outer shell), and three-dimensional (3-D) (coupled-layer MWNTs). Electronic modification of carbon nanotubes by insertion of C_{60} and other fullerenes into the central capillary to form a mixed-dimensionality hybrid structure called the *peapod* is a science in its infancy but promises a rich future for research and applications [50.5].

Carbon nanotubes are chemically stable in ambient conditions and structurally stable in vacuum for temperatures far greater than 1000°C . Viewed in total, the above properties potentially make carbon nanotubes excellent electronic materials. For some nanoelectronic applications the major drawback is perhaps insufficient control of the synthesis process – presently the focus of much worldwide research effort – and contacting of in-

dividual nanotubes is poorly understood. Nevertheless, the range of proposed electronic applications is vast. These considerations place carbon nanotube electronics among a number of competing technologies poised to complement or replace silicon-based complementary metal–oxide–semiconductor (CMOS) technology in the < 100 nm-feature-size domain.

50.1.2 Geometry

The unique feature of the electronic structure of carbon nanotubes is that it can range from the metallic to the semiconductor depending on the details of the microstructure. Essentially, the way the hexagonal network connects to itself to form a cylinder determines the electronic structure: the chiral vector usually used to describe the wrapping of the network is

$$\mathbf{C} = n\mathbf{a}_1 + m\mathbf{a}_2 \equiv (n, m),$$

where \mathbf{a}_1 and \mathbf{a}_2 are the unit vectors of the hexagonal network, and n and m are integers. The resulting nanotube can then be described in the form (n, m) . Electronic band-structure calculations show that an (n, m) nanotube is metallic at room temperature if $2n + m$ is a multiple of 3, otherwise it is a semiconductor with a band gap of $E_g = 0.9 d \text{ eV}$, where d is the nanotube diameter in nanometers, i. e. typically $E_g \approx 0.5 \text{ eV}$. This remarkable property signals the possibility of band-gap engineering by control of the microstructure. The wrapping angle, or chiral angle, is given by the angle between \mathbf{a}_1 and \mathbf{C} . From geometric and symmetry considerations, $0 < |m| < n$, $0^\circ = \theta = 30^\circ$, $\cos(\theta) = 2n + m / [2\sqrt{n^2 + m^2 + nm}]$, and nanotube diameter $d = 0.078\sqrt{n^2 + m^2 + nm}$ nanometers. The general case (n, m) is referred to as the chiral nanotube; there are two special cases: (a) the zigzag nanotube ($m = 0$, $\theta = 0^\circ$), and (b) the armchair nanotube ($n = m$, $\theta = 30^\circ$, all metallic) [50.2].

Some degree of control of diameter and length is possible at present but very limited control of chirality, and therefore electronic structure, is achievable now. Assuming a random distribution of nanotube diameters in the reaction products, the relative populations of metallic to semiconducting electronic structure is 1:3. Single-symmetry (n, m) synthesis or post-synthesis sorting according to electronic structure are key fields for research effort. The task is proving rather difficult but there appear to be no fundamental barriers to progress.

A stable defect in the hexagonal network is the pentagon–heptagon pair (Stone–Wales or 5–7 defect). This defect will cause a sharp bend in an otherwise well-graphitised SWNT. Controlled introduction of defects

allows the possibility of constructing Y- and T-junctions and other complex geometries from nanotubes, including rings and coils. Moreover, a 5–7 defect can connect a metallic to a semiconductor nanotube giving an Angstrom-scale heterojunction and hence a device density 10^4 times greater than present-day microelectronics [50.6].

50.1.3 Synthesis and Chemistry

The quality of carbon nanotubes in terms of crystallinity and impurity content depends on the conditions of synthesis by arc discharge using graphitic electrodes, laser vaporisation of graphite, or chemical vapour deposition (CVD) using hydrocarbon gas and metal nanoparticle catalysts. Each method produces different nanotube samples and sample-to-sample variation from the same source. An extensive review of synthesis methods was published by Rakov [50.7]. The key factor for crystallinity, and therefore electronic quality, is the formation temperature: $> 2000^\circ\text{C}$ is required for complete graphitisation. Little is known about the preferences the various growth processes have for certain nanotube symmetries over others.

Reaction products can contain significant quantities of residual metal catalyst particles and non-tubular forms of carbon (typically 30 wt % of the raw material). Purification processes ranging from the simple to complex are commonly used: oxidation and acid washing [50.8], solvent treatment followed by ultrafiltration [50.9], or flocculation using aqueous surfactants [50.10]. Controlled growth of MWNTs perpendicular to a substrate has been widely explored due to its technological importance [50.11].

Surface functionalisation of SWNTs is required for several applications as a means of modifying charge exchange with the ambient. Oxidation of nanotubes with the acid mixture $\text{H}_2\text{SO}_4\text{--HNO}_3$ leads to high concentrations of carboxylic, carbonyl, and hydroxyl groups on the surface and removal of the tips to expose the interior surface. Carboxyl ($-\text{COOH}$) groups are then readily derivatised by a variety of reactions. Covalent functionalisation, however, necessarily disrupts the rigid structure and π -electron system with consequent degradation of mechanical and electrical properties but provides the best stability and accessibility [50.12]. Non-covalent routes to nanotube functionalisation offer ease of synthesis and minimum disruption of the tubular structure [50.13].

Exposure to ambient humidity, oxygen and other gases profoundly affects the measured electronic prop-

erties of nanotubes through charge exchange and the quality of metallic electrical contacts made to nanotubes. The electronic properties of carbon nanotube systems are extremely sensitive to the presence of molecular oxygen due to the formation of the charge-transfer complex $C_p^{+\delta}-O_2^{-\delta}$, i. e. oxygen-exposed nanotubes are p-type [50.14]. Nanotubes exhibit ultrahigh sensitivity at room temperature to O_2 , N_2O , NH_3 but not H_2 [50.15]. Nanotubes must be elevated to temperatures $> 700^\circ C$ in ultrahigh vacuum to completely remove absorbents.

50.1.4 Electronic Structure and Transport

The electronic structure of SWNTs is predicted by tight-binding calculations extended from the 2-D approach for graphite to the cylindrical 1-D nanotube system [50.2]. In the case of nanotubes circumferential crystal momentum vectors are quantised due to the periodic boundary conditions imposed by a finite nanoscale diameter. This simple approach has been proven, mainly by low-temperature scanning tunnelling spectroscopy, to be a good description of the electronic structure of carbon nanotubes [50.16]. The curvature of the nanotubes is ignored in this model but can introduce some important modifications [50.17]. However, the original model is, nevertheless, adequate for the classification of nanotubes into metallic and semiconducting types according to the simple rule outlined in Sect. 50.1.1. In common with other 1-D conductors with half-filled bands the expectation was that carbon nanotubes will undergo a Peierls distortion, i. e. and a gap will open in the band structure at the Fermi energy due to atomic displacement modifying the unit cell. However, it has been shown theoretically that the effect very quickly diminishes as a function of nanotube radius [50.2].

Electrical transport measurements on individual SWNTs, SWNT ropes, and MWNTs have produced diverse results in the decade since discovery and are still the focus of intense research effort. The picture is complicated by several factors:

1. the current pathway through MWNTs is greatly complicated by interlayer coupling,
2. two-terminal resistances in the range $100\ \Omega$ – $100\ M\Omega$ were first reported [50.18],
3. the processing, contacting, and manipulation methods used undoubtedly introduced non-intrinsic resistances and potential barriers.

Nevertheless, the best transport parameters that have emerged since discovery, quoted in Sect. 50.1, are highly

desirable from many device points of view. The quality of lithographically defined contacts is critical for electrical transport measurements. There are three possible outcomes of the contacting process:

1. the contacts are of good quality; then the total resistance will be the diffusive or quantum resistance for that structure ($6.5\ k\Omega$ for a ballistic SWNT) [50.19];
2. no contact is made and the nanotube is isolated by tunnel barriers; in this case the nanotube will act as a Coulomb island and blockade phenomena will be observed at low temperature [50.20],
3. the contacts are of an intermediate type that allows the nanotube to act as a cavity and Fabry–Perot interference phenomena are observed [50.21].

The exact physics of contacting to carbon nanotubes is poorly understood; the exact atomic arrangement at the interface is likely to play a role as are the ambient gases.

Successful transport measurements have yielded a plethora of quantum-electronic and low-dimensional transport phenomena. *Tans* et al. [50.19] demonstrated true quantum wire behaviour; the remarkable feature of this work was to identification of an electron phase-coherence length on the micrometer scale at 4 K for nanotubes: several orders of magnitude greater than that in conventional semiconductor nanostructures. With an extraordinarily skilful experiment *Bachtold* et al. [50.22] demonstrated the Aharonov–Bohm effect by circulating circumferential current in a contacted MWNT with the axis parallel to a magnetic field. The periodicity of the magneto-conductance variation with applied field corresponded to an interferometer diameter equal to that of the outer MWNT shell. This finding gave weight to an earlier conclusion from quantum conductance measurements of *Frank* et al. [50.23], namely that current is only carried in the outer shell for MWNTs. This was posed as a general statement but was contradicted by the controlled layer-by-layer conductivity analysis of *Collins* et al. [50.24] in which the current-carrying contribution of each MWNT layer was determined by vaporisation of successive MWNT layers. This work concluded that at least eight layers contribute to the current-carrying capacity of a MWNT. The nature of MWNT inter-layer coupling is a point of discussion at present.

The landmark paper of *Frank* et al. identified ballistic conductance in MWNT systems at room temperature by controlled lowering of a MWNT bundle into a liquid mercury contact [50.23]. This was a remarkable result since the implication is that the electron mean free path is on the micrometer scale at room temperature. A ballis-

tic conductor has a conductance given by the Landauer formula:

$$G = 2 \left(\frac{e^2}{h} \right) \cdot \sum_i^N T_i,$$

where N is the number of conducting channels, T is the transmission factor (experimental result: $T = 1$ for most nanotube systems), and $G_0 = 2e^2/h$ is the quantum conductance (the factor of 2 is due to spin degeneracy). Frank et al. measured a conductance of $1G_0 >$ per MWNT, implying that current is carried in the outer shell only and there is a *missing* $1G_0$ since a metallic carbon nanotube has two crossing 1-D energy bands at the Fermi level, which yields a conductance of $2G_0$ for a single nanotube shell. However, more recent results have shown the expected $2G_0$ result [50.21]. Therefore, the controversy over the experiment by Frank et al. remains unsolved.

SWNTs were expected to exhibit the predicted electron–electron interaction effects in 1-D systems, the so called Luttinger liquid (LL) state. In a strictly 1-D system the independent electron approximation breaks down and the normal 3-D Fermi gas picture is replaced by the LL. In the LL description electron–electron interactions dominate and the electrons are in a highly correlated state. The LL state requires a high degree of order since disorder destroys the correlated ground state. The main features of the LL are suppression of the density of states at the Fermi energy according to a power law and separation of spin and charge excitations. In transport measurements, the LL state is manifested as a tunnelling conductance from a normal electrode according to $G(T) \approx T^\alpha$, for $eV \ll k_B T$, and at large voltages $G(V) = dI/dV \approx V^\alpha$ for $eV \gg k_B T$, where the parameter α is determined by the strength of the interaction between the electrons. Such power laws have been observed in contacted SWNTs, although stronger evidence, such as a clear demonstration of spin–charge separation, is necessary to identify the LL state unambiguously [50.25].

Coulomb blockade phenomena have been observed in low-temperature transport measurements on carbon nanotube systems often by unintentional incorporation of tunnel junctions between the metal electrode and the nanotube. The effect occurs when a mesoscopic *island* with capacitance C (self-capacitance of the nanotube plus the barrier capacitance at the nanotube–electrode junction) is isolated by tunnel barriers from two electrodes. If the charging energy for a single electron on the island, e^2/C , is larger than the thermal energy $k_B T$, then

the system will not conduct due to electron–electron repulsion. Coulomb blockade can be modulated by a gate electrode from full blocking to a conducting state limited only by the tunnel barriers. Such a system forms a single-electron transistor (SET). The capacitance of a nanotube is $\approx 10^{-17}$ F, thus SET operation conditions are fulfilled at temperatures below 10 K when the entire nanotube defines the Coulomb island. To minimise the capacitance and therefore elevate the operating temperature inter-tube islands can be defined by crossing nanotubes or intra-tube islands bending with a scanning probe microscope (kinks and bends in SWNTs can create tunnel barriers). The latter approach has been used to create a SET that operates close to room temperature [50.26].

Superconductivity in nanotube systems was first observed as the proximity effect with SWNTs or SWNT ropes connecting two superconducting electrodes [50.27]. The first report signalling intrinsic superconductivity in SWNT ropes was a recent landmark publication [50.28]. This will clearly spur further experimental and theoretical effort.

50.1.5 Nanoelectronic Devices

Semiconducting nanotubes are especially important for nanoelectronic device applications. Semiconducting behaviour has been observed in individual SWNTs; in SWNT ropes and MWNTs mixed metallic and semiconducting current pathways greatly complicate the I – V characteristic. Field-effect transistors (FETs) with individual SWNT channels have been demonstrated and found to have higher transconductance than can be achieved with state-of-the-art metal–oxide–semiconductor field-effect transistors (MOSFETs) [50.29]. The conducting state is attained with negative gate voltages, implying that the carbon nanotube forms a normally off p-type conduction channel (probably due to unintentional doping by exposure to oxygen). Logic gates made from nanotube FETs have been recently demonstrated [50.30]. The nature of the metal electrode–SWNT Schottky barrier is still not fully understood.

The prospects for highly integrated circuits consisting of nanotube elements must be considered remote at this time for several reasons (some previously mentioned):

1. current synthesis techniques produce mixtures of metallic or semiconductor nanotubes and these tend to form ropes or bundles;

2. the precise nature of the metal electrode–nanotube contact is poorly understood; and
3. scanning probe manipulation techniques used to fabricate prototype individual devices are not scalable.

50.1.6 Other Electronic Applications

Although nanoelectronics has been the driving force for carbon nanotube research, many other electronic applications are being explored; this section outlines some of them.

Interconnects

Ballistic transport on the micrometer scale at room temperature and high current-carrying capacity suggests carbon nanotubes are good candidates for high-bandwidth dissipation-less interconnect for nanoscale circuit elements. Since chemical processing tends to degrade nanotube electrical properties, methods of directed growth are being explored as a means of *wiring* integrated circuits, e.g. guiding through via holes [50.31], by electric field [50.32], or surface modification [50.33].

Field-Emission Displays

The nanoscale diameter, aspect ratio of ≈ 1000 , and high conductivity make carbon nanotubes ideal candidates for field emitters [50.34]. Field-emission currents from single nanotubes and aligned or randomly oriented nanotube thin films have been extensively studied. The promise is of low-threshold-field electron emission with a current density sufficient to drive a phosphor screen for display purposes. SWNTs and MWNTs have proved to be remarkably good field emitters with threshold emission fields in the range $1\text{--}10\text{ V}/\mu\text{m}$ and capable of carrying very high current density. The exact emission mechanism, the role played by surface absorbents, and the cause of emission current saturation are under debate. Nevertheless, major manufacturers have recently produced prototype field-emission displays with carbon nanotube sources; with further development, this is likely to be the first major application of carbon nanotubes to reach the marketplace [50.35].

Electron-Beam Lithography

The present minimum feature size for silicon microelectronics is 130 nm, which is achieved using extreme-UV optical lithography. Alternative technologies are being explored for the future production of $< 100\text{ nm}$ devices. Conventional electron-beam lithography can achieve a 5-nm line width but is limited by writing time because a single beam is used to write the entire pattern. Thus

arrays of electron guns operating in parallel are being considered as a route to reduction of the writing time while maintaining the high resolution of electron-beam lithography. Carbon nanotubes are currently the most promising candidates for use as the emission source [50.36].

Electro-Optic Materials

Polymer–nanotube composite materials have been studied from the point of view of applications in electro-optics. Loading the layers of organic light-emitting diodes (LEDs) with low concentrations of nanotubes effectively increased the lifetime of the devices by preventing the build up of local hot spots thorough the high thermal conductivity that can be achieved in a nanotube percolation network [50.37]. Nanotube-induced local ordering of the matrix polymer suggests efficiency improvements may also be possible [50.38]. Using nanotube mats as an electrode in solar-cell applications apparently gave no improvement in device performance; however, these early measurement were performed with defective MWNTs so there may be a case for further investigation using the high-quality SWNTs available today.

Nanofabricators

Carbon-nanotube atomic force microscopy tips for fabricating oxide nanostructures in Si and Ti by anodisation is a rapidly expanding field aimed at Tbit/cm^2 data storage [50.39]. The technique utilises ambient moisture in the oxidation process with the tip biased negative relative to the surface. Line widths of $5\text{--}10\text{ nm}$ suitable for antidotes and tunnel junctions can be achieved.

Actuators

Electromechanical actuators based on SWNT sheets have been shown to generate higher stresses than natural muscle when operating in physiological conditions and higher strains than high-modulus ferroelectrics [50.40]. The actuation mechanism is a geometrical expansion of the carbon–carbon covalent bond caused by electrochemical double-layer charging. Work densities per cycle substantially higher than any previously known technology are predicted for SWNT sheets with mechanical properties close to those of individual SWNTs. This can be achieved by inter-tube binding and alignment optimisation.

Sensors

The conductivity of nanotube systems is highly sensitive to gaseous ambients, which affect the sign and

amount of injected charge. The dimensions of a nanotube sensing element is such that very low quantities of analyte species will produce a measurable response. Nanotube gas sensors certainly have prospects to challenge conventional gas sensors for certain uses [50.15].

50.2 Bucky Materials

Over the last decade the field of bucky materials has been dominated by carbon nanotubes, as the number of publications and patent submissions testify. After intense research activity since their discovery, the most noteworthy of C_{60} -based electronic materials are superconducting heterofullerides of composition K_2MC_{60} , where $M=Fe, Ni, Cu, Ag, Co \dots$, with $T_c \approx 15$ K. However the future for encapsulation of species in the C_{60} , and higher fullerene, cage ap-

In addition to transduction, bio-sensors require a bio-receptor (e.g. enzyme or cell) immobilisation matrix. Carbon-nanotube-based bio-sensors meet both requirements and have been found to promote homogeneous electron-transfer reactions.

pears promising, in particular as the basis of devices for quantum information processing. Other non-carbon-nanotube structures are now under intense investigation; these include BN, W, MoS_2 , heterogeneous nanotubes and the ternary compound $Mo_6C_{9-x}H_x$ (C =chalcogen, H =halogen, $3 < x < 6$). The science of these structures is still in its infancy but, given the rich experience of over a decade of carbon nanotube research, there is reason to be optimistic of exciting new science and technology.

51. Magnetic Information-Storage Materials

The purpose of this chapter to review the current status of magnetic materials used in data storage. The emphasis is on magnetic materials used in disk drives and in the emerging technology of the magnetic random-access memory (MRAM). A wide range of magnetic materials is essential for the advance of magnetic recording both for magnetic recording heads and media, including high-magnetization soft-magnetic materials for write heads, new antiferromagnetic alloys with high blocking temperatures and low susceptibility to corrosion for pinning films in giant-magnetoresistive (GMR) sensors and new ferromagnetic alloys with large values of giant magnetoresistance. For magnetic recording media, the advances are in high-magnetization metal alloys with large values of the switching coercivity. A significant limitation to magnetic recording is found to be the superparamagnetic effect and new advances in multilayer ferromagnetic films to reduce the impact of the effect, but also to allow high-density recording have been developed.

Perpendicular recording as compared to longitudinal recording is reviewed and it is shown

that this technology will be the dominant recording technology in the future. The MRAM device uses some of the same materials as used in the GMR sensor, but the key technology is the magnetic tunneling junction in which soft-magnetic films are coupled by a thin insulating film and conduction is by quantum-mechanical tunneling. The status of the MRAM technology and some of the key problems are reviewed.

The purpose of this chapter is to summarize the status of magnetic materials used in high-capacity disk drives and magnetic-semiconductor memory devices. The technology of disk drives is selected since these devices have experienced the largest increase in data capacity over time and this has made disk drives the pre-eminent storage system for digital data. To illustrate this point, consider Fig. 51.1, which is a plot of the areal density (number of data tracks per inch times the number of bits per inch recorded on a track) for disk drives over time [51.1]. The increase in areal density is more than 100% per year up to about 2002, when it reduced to about 20–30%. At the time of writing the areal density being shipped in disk drives is close to 130 Gb/in². The total data capacity of a disk is approximately the areal density times the recording area, which depends on the size of the disk [2.5 and 3.5 inches (64 and 90 mm)] diameter

being the most common. Many technologies have contributed to this rapid increase in areal density, including advances in the technology of *flying* heads with reduced spacing to the disk surface, data codes and error detection and correction, advanced servo control systems for accurate control of magnetic recording heads on data tracks, and improvements in the mechanical structures comprising a disk drive, including advances in motors used to drive the disks. However, this paper discusses only the fundamental technology associated with digital magnetic recording, including the devices used to record and read back the recorded data and the media on which the data is recorded. The discussion is also restricted to the materials and not to any of the mechanical structures associated with the recording heads or disks. The discussion covers conventional longitudinal magnetic recording as used in present (and past) disk drives

Fig. 51.1 IBM areal density perspective. (After [51.1])

and the emerging technology of perpendicular magnetic recording, in which the remanent magnetization is per-

pendicular to the disk surface, and which reduces the impact of the superparamagnetic limit (to be discussed). We will not discuss some variants of longitudinal magnetic recording, e.g., thermally assisted recording and patterned media.

Recently there has been a significant new emerging technology for fast memory devices – magnetic random-access memory (MRAM). The MRAM device is a possible replacement for the familiar semiconductor memories used in modern computers – dynamic and static random-access memory (DRAM and SRAM). The MRAM technology combines a magnetic storage technology together with metal-oxide semiconductor (MOS) devices to result in fast and high-density data memory devices. The technology on which the magnetic part of MRAM is based is an extension of the technology used in magnetic recording devices – the magnetic tunneling junction (MTJ). The MRAM technology will also be discussed in this paper. Parts of this chapter have been previously published in the *Journal of Materials Science: Materials in Electronics* [51.2].

51.1 Magnetic Recording Technology

The technology of magnetic recording was one hundred years old in 1999 [51.3]. The fundamental concept of magnetic recording is to use a magnetic structure (the *write head*) driven by current which represents the data to be recorded to generate a magnetic field which can change the state of the magnetization in a closely spaced magnetic recording medium, which in the earliest realization was magnetic wire, and today is either

the familiar magnetic tape or a magnetic layer on a rigid disk substrate. The data are recovered by the generation of an output voltage in the *read head* by sensing the magnetization in the recording medium, e.g., by Faraday's law ($V = N \frac{d\Phi}{dt}$), where N is the number of turns on the read head and Φ is the magnetic flux coupled to the read head from the media. The magnetic recording system to be discussed here is that used to store digital data, in which case the current supplied to the write head is in the form of pulses encoded to represent the digital data (1s or 0s) [51.4, 5]. In the case of disk drives the

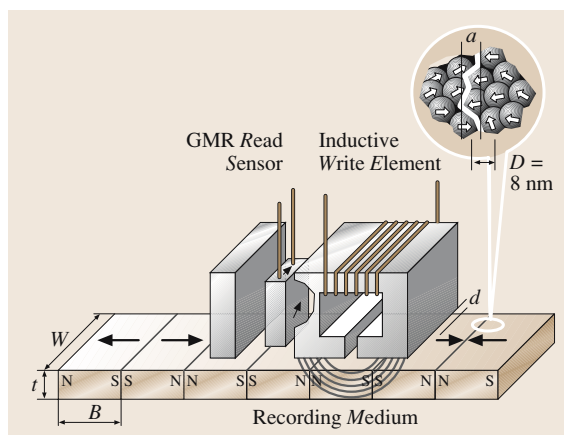

Fig. 51.2 Schematic illustration of a longitudinal magnetic recording system showing a giant magnetoresistive (GMR) read sensor, write element and the recording medium. The parameters are: t the recording medium thickness (δ is also used), W the width of the recorded track, B the length of the recorded magnetization or bit size and d the magnetic spacing (includes overcoats on the disk surface and undercoats on the slider surface). Shown in the *inset* is the transition region between the two directions of the magnetization; D is the media grain size and a is the transition parameter that characterizes the length of the transition region (length $l = \pi a$). (After [51.1])

write and read heads are separate thin-film structures deposited on the back of a mechanical slider, which uses a hydrodynamic air bearing to fly over the surface of the disk [51.5]. Figure 51.2 is a schematic of a modern digital magnetic recording system. The recording (*write*) and read elements are shown together with the magnetic recording surface which in modern disk drive technology is a thin metallic film of a cobalt alloy (to be discussed). The digital data are recorded in the magnetic film as *transitions* between the two possible states of the magnetization (pointing to the *left* or *right*) and with the width approximately equal to the width of the write head and the width of a data track. The transition region between the oppositely directed directions of the magnetization is similar to that between magnetic domains and has a length l . We will discuss the different parts of the recording system starting with the write head and including the read head which in Fig. 51.2 is a giant-magnetoresistive sensor. First, we will discuss some aspects of thin magnetic films that are relevant to magnetic recording components. All magnetic recording components used in disk drives today are fabricated from thin films to allow mass production and for technology reasons, as we will discuss.

51.1.1 Magnetic Thin Films

Induced Uniaxial Anisotropy

In most applications of soft-magnetic films a uniaxial anisotropy in the plane of the film is required. One way of introducing this uniaxial anisotropy is to induce it by applying a magnetic field in the plane of the film and the effect is referred to as magnetic annealing. The anisotropy can be induced during deposition of the film or induced by a subsequent annealing step, using temperature and a magnetic field to modify the anisotropy. The mechanism of the induced anisotropy is that of directional order, in which atomic pairs in an alloy tend to align with the local magnetization. In nickel-iron films the atomic pairs are the iron atoms and the induced uniaxial anisotropy energy density is typically $K_u \cong 1\text{--}3 \text{ kerg/cm}^3 (0.1\text{--}0.3 \text{ kJ/m}^3)$, where the uniaxial energy density is

$$E_k = K_u \sin^2 \theta, \quad (51.1)$$

where θ is the angle of the magnetization with respect to the direction of the induced anisotropy. To induce the anisotropy it is necessary to saturate the magnetization of the film with a small magnetic field, typically 50–100 Oe (4000–8000 A/m), since it is the magnetization not the magnetic field that is responsible for the

magnetic annealing. If the anisotropy energy density is positive the energy is minimum is along the direction of the anisotropy, which is referred to as an *easy* axis.

A second method of introducing uniaxial anisotropy in thin films is by stress. If the magnetostriction constant is isotropic with value λ_s for a polycrystalline material then the magnetoelastic energy density is given by

$$E_{me} = \frac{3}{2} \lambda_s \sigma \sin^2 \theta. \quad (51.2)$$

The angle θ is the angle of the magnetization in the film plane with respect to the direction of the stress (σ). If a sample is unmagnetized it will strain by λ_s as the sample is magnetized to saturation. A typical value of λ_s is $\approx 10^{-6}$. If the magnetostriction constant and the stress are both positive the direction for the minimum energy and hence the easy axis is for $\theta = 90^\circ$. The magnetization, permeability, crystalline anisotropy constant and magnetostriction constant of nickel-iron alloys $\text{Ni}_x\text{Fe}_{(1-x)}$ are shown in Fig. 51.3 [51.6]. The maximum permeability is for the Permalloy composition $\text{Ni}_{80}\text{Fe}_{20}$. Increasing the atomic percentage of iron over that of Permalloy results in increased magnetization since the magnetic moment for iron is $2.2 \mu_B$ (Bohr magnetons) per atom in the metal, while the value for nickel is $0.6 \mu_B$ per atom in the metal.

Hysteresis in Soft-Magnetic Films

If we impose an external magnetic field H_e along the direction of the induced anisotropy (easy axis) of the thin film ($\theta = 0^\circ$) the total energy density is given by

$$E_k = K_{\text{eff}} \sin^2 \theta - MH_e \cos \theta.$$

K_{eff} is the sum of the uniaxial crystalline anisotropy (K_u) and the stress anisotropy ($3/2 \lambda_s \sigma$). The second term is the magnetostatic energy. The equilibrium angle for the magnetization is given by minimizing the total energy,

$$\frac{dE}{d\theta} = 2K_{\text{eff}} \sin \theta \cos \theta + MH_e \sin \theta = 0.$$

The solution $\sin \theta = 0$ implies that the magnetization lies at either $\theta = 0$ or 180° . However, the energy must be a minimum for stability and the second derivative changes sign at a boundary between stability and instability

$$\frac{d^2E}{d\theta^2} = 2K_{\text{eff}}(\cos^2 \theta - \sin^2 \theta) + MH_{e,\text{crit}} \cos \theta = 0.$$

The magnetic field which just satisfies this condition is

$$H_{e,\text{crit}} = -H_c = -\frac{2K_{\text{eff}}}{M}. \quad (51.3)$$

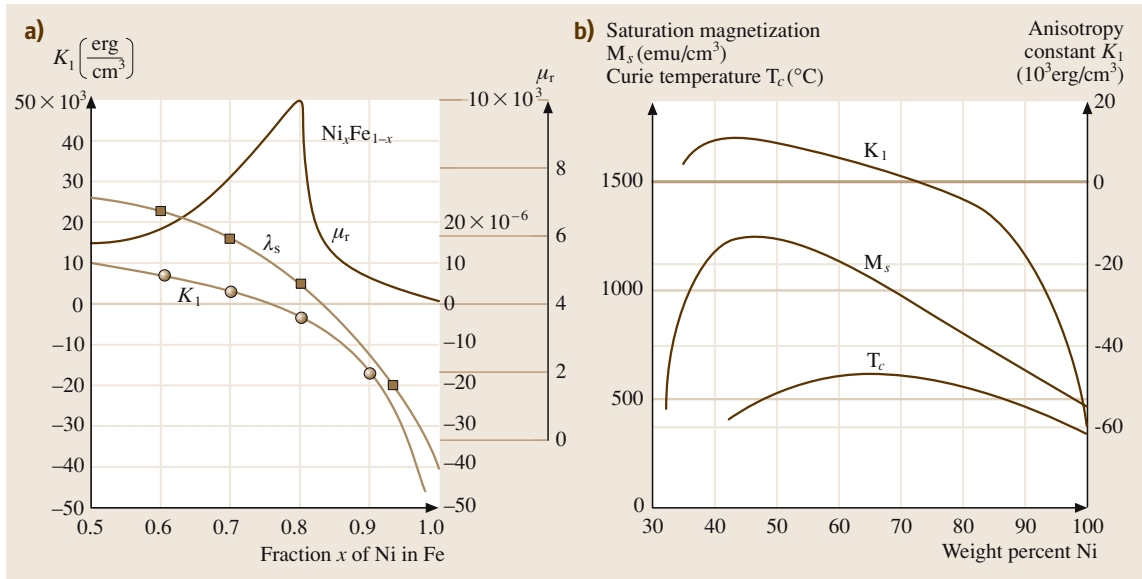

Fig. 51.3 (a) Magnetic properties of $\text{Ni}_x\text{Fe}_{1-x}$ alloys, including initial permeability, crystalline anisotropy and magnetostriction. (b) Magnetization, Curie temperature and crystalline anisotropy of $\text{Ni}_x\text{Fe}_{1-x}$ alloys. (After [51.6])

The critical magnetic field is the coercive field (H_c). A curve of the magnetization versus applied magnetic field for this case is shown in Fig. 51.4 (curve labeled “easy”), which was measured on a thin film of FeCoNi (to be discussed) [51.7]. The magnetization curve exhibits hysteresis and in the FeCoNi alloy the coercive field is small and the material is magnetically *soft*. Hysteresis is responsible for the use of magnetic materials as digital memory devices since the *up* or positive state

of the magnetization could represent a binary 1 and the *down* or negative state could represent a binary 0 and these states can be stable even in zero applied field ($H_e = 0$). The above analysis also applies to magnetically hard films, for which the coercive field is large. We will discuss magnetic recording media and here the coercive field is measured in units of kOe.

With the magnetic field applied perpendicular to the easy axis, along the hard axis, the energy density is given by

$$E_k = K_{\text{eff}} \sin^2 \theta - MH_e \sin \theta.$$

The derivative of the total energy is given by

$$\frac{dE}{d\theta} = 2K_{\text{eff}} \sin \theta \cos \theta - MH_h \cos \theta = 0$$

resulting in the two solutions

1. $\cos \theta = 0$, or $\theta = 90^\circ$ or 270° ;
2. $\sin \theta = \frac{H_h}{2K_{\text{us}}/M}$.

The solution to this case is also shown in Fig. 51.4 (curve labeled “hard”) and is seen not to exhibit hysteresis. This is the *hard-axis* magnetization curve and the magnetic field where the magnetization saturates is known as the anisotropy field H_k . The hard-axis magnetization curve is used extensively for magnetic recording heads.

Fig. 51.4 Easy and hard magnetization curves of an electroplated FeCoNi alloy film. (After [51.7])

Fig. 51.5 Thin film head with eight turns showing the poles and yoke structure. A is Permalloy, C is copper and E is baked photoresist. (After [51.13])

51.1.2 The Write Head

The write head is formed from thin films of soft ferromagnetic alloys patterned in the form of a magnetic yoke. A schematic of an eight-turn thin-film head is shown as Fig. 51.5 [51.13]. Heads in present disk drives typically have fewer than five turns to reduce inductance. The cross-hatched regions are the soft ferromagnetic material and the leads which carry the write current are shown on the right-hand side of the top view. Note that the widths of the copper alloy turns are increased near the back region of the head to reduce resistance. The heads are fabricated using electroplating and the substrate (not shown) is a hard ceramic that can be machined to form the slider [51.5]. Electrical current in the form of pulses is coupled to the yoke to generate a magnetic field at

the gap. The coil is insulated from the metallic magnetic yoke by layers of baked polymer photoresist. The alloy that has been used most frequently in the past for the magnetic films in the write head is $\text{Ni}_{80}\text{Fe}_{20}$ – Permalloy, which can be deposited in thin films using electroplating. Electroplating is discussed in Comstock [51.4] and in more detail by Andricacos and Romankiw [51.14]. The maximum coercivity ($H_{c,\max}$) of the recording medium that can be recorded by the write head is given by (51.4) (in cgs units) [51.4]

$$H_{c,\max} = 0.20 \times 4\pi M_s \tan^{-1} \left(\frac{g/2}{d + \delta} \right), \quad (51.4)$$

where $4\pi M_s$ (Gauss) is the saturation flux density of the material used in the recording or write head, g is the gap length of the write head, d is the magnetic spacing, which is the spacing of the head to the recording magnetic film (including any overcoat films on the recording heads and recording medium) and δ is the thickness of the recording film (shown as t in Fig. 51.2). To increase the linear density (transitions along a recorded track), it is necessary to increase the coercive field of the recording media. This is the case since the length of a transition between the two states of the magnetization is given by (51.5) (in cgs units) [51.15] and [51.4].

$$l = \pi a = \pi \left(\frac{d(1 - S^*)}{\pi Q} \right) + \left[\left(\frac{d(1 - S^*)}{\pi Q} \right)^2 + \left(\frac{2M_r \delta}{H_c} \right) \left(\frac{2d}{Qr} \right) \right]^{1/2}, \quad (51.5)$$

where $S^* = 1 - \frac{M_r/H_c}{dM/dH(H=-H_c)}$ quantifies the slope of the hysteresis curve of the recording medium at the coercive field and $Q = \frac{dH_x/dx}{H_c/d}$; Q is the normalized slope of the horizontal component of the write-head magnetic field at the value $H = H_c$. A typical value of Q is 0.7.

Table 51.1 Properties of materials used in magnetic recording heads

Material	B_s (kG) ($\text{T} \times 10^{-1}$)	μ_r	ρ ($\mu\Omega\text{cm}$)	H_c (Oe) (A/m)	References
$\text{Ni}_{80}\text{Fe}_{20}$ (Permalloy)	10	1500–3000	20	0.1–0.5 (7.95–39.78)	[51.6]
Sendust (FeSiAl)	10	8000	85	0.25 (19.9)	[51.4]
$\text{Ni}_{45}\text{Fe}_{55}$	16	1700	48	0.3 (23.87)	[51.8]
$\text{Co}_{48}\text{Ni}_{22}\text{Fe}_{30}$ electroplated with pulsed plating	21.5	1000	–	≈ 1 (79.6)	[51.9]
$\text{Co}_{56}\text{Ni}_{13}\text{Fe}_{31}$ (C) electroplated with carbon impurity	19	–	≈ 70	≈ 2 (159.2)	[51.10]
$\text{FeAl}(2\%\text{Al})\text{N}$ (N/Fe 6.6%) sputtered	20	2450	38	3.8 (302.4)	[51.11]
FeTiN sputtered	18–21	–	–	≈ 5 (397.9)	[51.12]

M_r (emu/cm³) is the remanent magnetization of the recording medium with thickness δ .

From (51.4) and (51.5) it is seen that for reduced transition length (and hence higher linear density) it is necessary to increase the coercive field (H_c) of the recording medium but to do so requires a concomitant increase in the magnetization of the write head (51.4). Materials with magnetization larger than Permalloy [$4\pi M_s = 10$ kG ($M_s = 1$ T)] and which are magnetically soft (large permeability) are listed in Table 51.1. The most common material used in present disk drives is electroplated Ni₄₅Fe₅₀, with a saturation magnetization of $4\pi M_s = 16$ kG ($M_s = 1.6$ T) [51.8]. Ternary alloys of Ni, Fe and Co also can be electroplated with saturation magnetization of $4\pi M_s \geq 20$ kG ($M_s = 2$ T). The composition region that results in the largest value of saturation magnetization but also large permeability is: Co_{48–56}Fe_{30–31}Ni_{22–13} (Table 51.1). A useful guide to the selection of the composition of the ternary FeCoNi alloys is the composition diagram shown as Fig. 51.6 [51.6]. The data for Fig. 51.6 were accu-

mulated in bulk materials. In a study of electroplating FeCoNi alloys for write heads [51.7] care was taken to avoid any impurities in the plating bath and the results showed the possibility of achieving $4\pi M_s$ values in the range of 21–21.5 kG and $H_c < 2$ Oe in the same region of the composition diagram (approximately Fe₃₅Co₄₅Ni₂₀). However, experiments in a larger cell in conditions closer to those in a manufacturing plating system and with higher Fe content and an organic additive ascorbic acid used to reduce the formation of Fe³⁺ showed even larger values of $4\pi M_s$ (> 2.2 kG) but with increased coercivity (> 8 Oe) [51.16]. The composition of ferromagnetic alloys can be selected to result in zero values for the magnetostriction constant and the Permalloy composition of nickel–iron alloys (Ni₈₀Fe₂₀) has a zero magnetostriction constant (Fig. 51.3). The magnetostriction constant is frequently chosen to be small and negative so that the magnetoelastic energy defines an easy axis at right angles to the direction of the stress [$\theta = 90^\circ$ in (51.2)]. In the case of thin-film write heads the stress is along the axis of the poles (upward in the

Fig. 51.6 FeCoNi saturation magnetization contours. (After [51.6])

Fig. 51.7 Maximum coercivity of recording media versus magnetic spacing (d) for write heads fabricated from Permalloy and from a magnetic material with saturation magnetization $2.5\times$ Permalloy

patterned yoke in Fig. 51.5) and with negative magnetostriction constant the easy axis is across the pole width, which means that the direction of flux flow is along the hard axis with the desired linear relation between the magnetization and the magnetic field (Fig. 51.4). In the case of the ternary alloys of FeCoNi an alloy composition that results in zero magnetostriction is $\text{Fe}_{13}\text{Co}_{31}\text{Ni}_{56}$, in which the nickel content is too high to be a useful write-head material [51.7].

Alloys of FeAl (2% Al) [51.11] and FeTi ($\approx 2\%$ Ti) [51.12] sputtered using a mixed N and Ar working gas offer desirable magnetic properties, as shown in Table 51.1, but have not replaced the electroplated alloys because of increased costs of sputtering. A material of interest for even higher values of saturation magnetization is the α'' phase of Fe_{16}N_2 , which has a potential of a saturation magnetization of 29 kG; however, this phase is metastable [51.18]. The actual values of saturation magnetization with this phase in thin-film form was 20 kG and required annealing at 200°C [51.18].

To record on recording media with increased coercivity is not the only issue with the magnetic materials used in write heads. It is also important that the write heads have high efficiency. Efficiency (η) in this case is defined as the ratio

$$\eta = \frac{H_g g}{N_w I}, \quad (51.6)$$

where H_g is the value of the magnetic field in the gap of the write head and I is the amplitude of the write

current pulse. High efficiency is important to allow write-current amplitudes that are easily supplied from integrated circuits. For high efficiency it is necessary that a large percentage of the magnetomotive force ($N_w I$) results in a magnetic field across the gap. However, the permeability of the yoke influences the efficiency

$$\eta = \frac{g/A_g}{g/A_g + l_c/\mu_r A_c}, \quad (51.7)$$

where A_g and A_c are the area of the gap and core, respectively; l_c is the length of the core and μ_r is the relative permeability of the core or yoke material. As shown in Fig. 51.3, the relative permeability (μ_r) of nickel-iron alloys drops for compositions different from the Permalloy composition. This decrease in the permeability of nickel-iron alloys with composition different from that for Permalloy is the direct result of the increase in crystalline anisotropy and magnetostriction, as shown in Fig. 51.3. The lower permeability of the FeCoNi alloys can be obviated in a design of the write head in which the high-magnetization films are used only in the gap region in a design referred to as a *stitched head*.

The values of coercivity of the recording medium (H_c) that can be recorded with recording heads with the saturation magnetization of Permalloy [$4\pi M_s = 10\text{ kG}$ ($M_s = 1\text{ T}$)] and materials with saturation magnetization 2.5 times that for Permalloy [$4\pi M_s = 25\text{ kG}$ ($M_s = 2.5\text{ T}$)] are shown versus the magnetic spacing (d) in Fig. 51.7. The magnetic spacing for recent technology demonstrations has reached a value of 15 nm (carbon overcoat for head – 3 nm, pole tip recession tolerance – 3 nm, flying height – 5 nm, and media

Fig. 51.8 Trend in coercive field (H_c) and media flux ($M_r T$) versus areal density in Gb/in^2 for disk drives. (After [51.17])

carbon overcoat—4 nm). The trend in coercivity (H_c) and flux ($M_r\delta$ or M_rT) versus areal density in commercial disk media is shown as Fig. 51.8 [51.17]. We will discuss synthetic antiferromagnetic media (SAF) media later.

With the increased linear density associated with increased areal density in disk drives and with increases in the rotation speed of the disks, the rate at which data are recorded (and read back) has increased over time. This increase in data rate leads to a requirement that the magnetic fields in the gap of a write head switch in ever decreasing times. The switching time of thin magnetic films as used in write heads is limited by three factors: first, the fundamental switching time resulting from the fact that magnetic moments are always associated with angular momentum that cannot be changed instantaneously; second, the eddy currents associated with the changing magnetic fields both decrease the magnetic fields and slow down the switching speed, and third the inductance of the coil [51.21]. Data rates depend on the form factor of the disks and with high-end 3.5-in drives the data rates are larger than 50 Mb/s, while with 2.5-in drives the data rates are roughly one-half as large.

51.1.3 Spin Valve Read Head

The technology that has evolved for sensing or reading the flux emanating from transitions in thin-film disk

Fig. 51.9 The magnetoresistance of three $(\text{Fe}/\text{Cr})_n$ superlattices at 4.2 K. The thickness of the layers in angstroms is shown. (After [51.19])

media is the spin valve. This technology is based on the giant-magnetoresistive (GMR) effect discovered in France and published in 1988 [51.19]. GMR results when thin ferromagnetic films are coupled by an even thinner spacer film of a nonmagnetic transition metal. A curve of resistance normalized to that with no magnetic field applied versus magnetic field for arrays of ferromagnetic films of Fe with thickness of 30 Å (3 nm) coupled by Cr with thickness varying from 9–18 Å (0.9–1.8 nm) is shown in Fig. 51.9 [51.19]. The number subscripted to the parenthesis characterizing the magnetic and transition-metal films is the number of such films, which are referred to as *superlattices*. With no applied magnetic field, the two films were antiferromagnetically coupled; that is, the magnetizations in the two films are equal in magnitude and oppositely directed. The application of a large in-plane magnetic

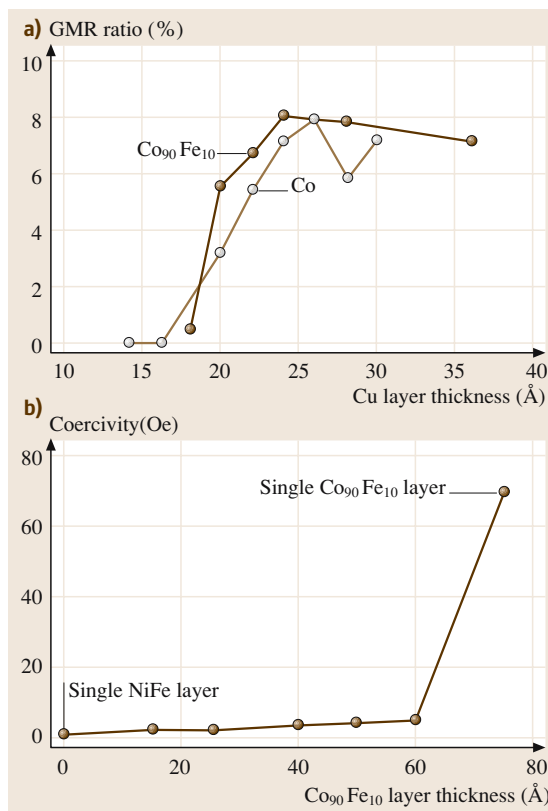

Fig. 51.10 (a) Comparison of GMR ratio ($\Delta\rho/\rho$) as a function of copper layer thickness in $\text{Co}_{90}\text{Fe}_{10}$ and Co films (see text). (b) Coercivity as a function of $\text{Co}_{90}\text{Fe}_{10}$ layer thickness in Ta (50 Å)/ $[\text{Ni}_{80}\text{Fe}_{20}/\text{Co}_{90}\text{Fe}_{10}]$ (75-Å) films. (After [51.20])

field rotated the magnetization of the coupled films to a parallel configuration, reducing the resistance (to be discussed). The current used to measure the magnetoresistance – the change in resistance with applied magnetic field – is applied in the plane of the films. This orientation of current is referred to as current-in-plane (CIP). Later we will discuss an alternative orientation of the current – current-perpendicular-to-plane (CPP). The initial discovery of **GMR** was done with a temperature of 4.2 K and the magnetic fields applied were measured in kOe ($10^6/4\pi$ A/m). The large change in resistance with magnetic field was in contrast to that observed in the anisotropic magnetoresistance (AMR) effect, which is the change in resistance observed when the magnetization in a *single* ferromagnetic film is rotated from an easy toward a hard axis. This latter technology – for which the resistance change with Permalloy was of the order of 2–3% – was being used in read heads during the time of research on the **GMR** effect. By the early 1990s it was found possible to observe **GMR** in other film materials with increased spacer film thickness at 300 K and with magnetic fields of tens of Oersteds. For example, the **GMR** ratio for two coupled films of an alloy of cobalt and iron ($\text{Co}_{90}\text{Fe}_{10}$ for which the magnetostriction constant is zero) with a variable thickness of the spacing layer of copper is shown in Fig. 51.10a [51.20]. It is seen that the **GMR** ratio is considerably reduced from that for the Fe/Cr superlattices at 4.2 K (Fig. 51.8) but the ratio is larger than that for the AMR effect. The discovery of the **GMR** effect led to the invention of the *spin valve read head*, in which one of two ferromagnetic films coupled by a thin transition-metal film is maintained constant in direction (the *pinned* film) and the orientation of the other film (the *free* film) is allowed to rotate (in the plane of the magnetic film), resulting in a decrease in resistance [51.22]. We will discuss the technology of pinning later. By free, it is meant that the magnetization in the film is easily rotated, e.g., by the magnetic field arising from transitions in the recording medium. It is surprising that cobalt is found to be useful in this application since cobalt is magnetically hard (pure cobalt metal has a high coercivity and is used in recording surfaces) and one of the requirements for the **GMR** effect is that the free film have high permeability and high efficiency (51.6). The reason for this result is shown in Fig. 51.10b, where the coercivity of a free film consisting of two films: $\text{Ni}_{80}\text{Fe}_{20}$ [60 Å (6 nm)] and $\text{Co}_{90}\text{Fe}_{10}$ is plotted versus the thickness of the $\text{Co}_{90}\text{Fe}_{10}$ film [51.20]. Even though the cobalt alloy would have a large coercivity in the bulk, the coercivity for thin films, together with the underlying $\text{Ni}_{80}\text{Fe}_{20}$ film, is low

for thicknesses less than about 60 Å. The advantage of the cobalt-iron film is the increased **GMR** ratio over $\text{Ni}_{80}\text{Fe}_{10}$. In order to increase the **GMR** ratio even more it has been found advantageous to deposit an interfacial nanolayer of cobalt metal on one or both sides of the free film [51.23]. We will learn in a discussion of the origin of **GMR** that cobalt has the potential for large **GMR** ratios.

A schematic of the spin valve read head is shown as Fig. 51.11 [51.22]. The magnetization of the free film is shown rotated to an angle θ_1 and the pinned layer is shown with a fixed angle of θ_2 . The pinning effect is due to the coupling of the pinned film to an underlying anti-ferromagnetic film as we will discuss. The nonmagnetic spacing layer separates the two ferromagnetic films. The maximum output voltage for the spin valve with no external resistance (and no reduction in the flux due to shielding (to be discussed) is

$$\Delta V = \eta J W_r \Delta \rho (1 - \sin \Delta \theta_1) / 2, \quad (51.8)$$

where η is the efficiency of the read head, which accounts for the fact that the angle θ_1 is not uniform over the height of the free film, J is the density of the current flowing through the films, W_r is the width of the read head (always less than the width of the written track) and $\Delta \rho$ is the change in resistivity of the stack of films with a change of θ_1 from -90° to $+90^\circ$, again with θ_2 fixed. The factor of 2 in the denominator is the result of the actual rotation of θ_1 being limited to 0° to 90° . The device senses magnetic field in the plane of the free film resulting from transitions in the recorded media ($H_{y,\text{disk}}$)

Fig. 51.11 Schematic of spin valve read element. The magnetization of the free layer is shown at an angle θ_1 to the easy axis (and direction of the current) and the magnetization of the pinned layer is fixed at 90° to this axis. (After [51.22])

through the rotation of the magnetization in the free film

$$\sin \theta_1 = \frac{H_{y,\text{disk}}}{H_k}, \quad (51.9)$$

where H_k is the anisotropy field of the free film (see analysis of the hard-axis magnetization curve in Sect. 51.1.1). In the absence of any other magnetic fields, the magnetization will lie along the easy axis. The hard axis is perpendicular to the easy axis. The voltage is measured across the lead terminals using a sense current and the width of the track is just the spacing between the leads. A typical value of peak output voltage per unit of track width for presently used spin valves is 15 mV/ μm . Spin valve read heads are shielded on each side of the stack of films to realize a narrow pulse width. The total width between the shields is G and the thickness of the stack of films comprising the spin valve is t . The read pulse is characterized by the amplitude but also by the width at one-half amplitude (PW_{50} in distance units) (discussed in [51.4])

$$PW_{50} \approx \sqrt{\frac{1}{2} (G^2 + t^2) + 4 (d + a + \delta/2)^2}, \quad (51.10)$$

where G is the total spacing between the shields and δ is the thickness of the recording layer.

The peak voltage amplitude with the shields with no external resistance can be approximated by

$$V_{\text{GMR}}(\text{peak}) = \frac{\eta I \Delta R_{\text{max}} M_r^{\text{rec}} \delta}{\pi t M_s^{\text{GMR}}} \left(\frac{(g+t)}{g} \right) \times 2 \tan^{-1} \frac{g}{2(d+a)},$$

$$I \Delta R_{\text{max}} = J W_{\text{read}} R_{\text{square}} t_{\text{sv}} \frac{\Delta R_{\text{max}}}{R_0}, \quad (51.11)$$

where η is the read efficiency, defined as the fraction of the flux sensed by the head to the total flux, M_r^{rec} is the magnetization of the recording layer, M_s^{GMR} the saturation magnetization of the free layer, g is the half-gap between the shields, R_{square} is the resistance per square of the stack of films comprising the spin valve and t_{sv} is the thickness of the free layer (modified from [51.24]).

Pinning with an Antiferromagnetic Film

For a spin valve to function, the pinned ferromagnetic film must have its magnetization perpendicular to the recorded track, as shown in Fig. 51.11 (the vertical magnetic field from the transitions in the disk is in the y -direction). This orientation of the magnetization in

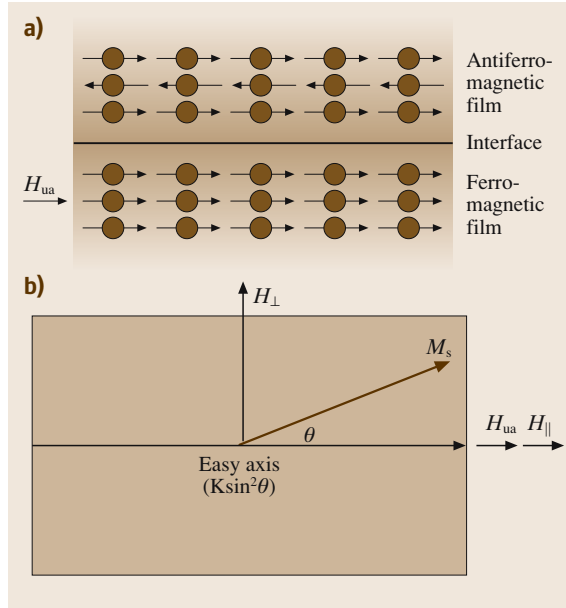

Fig. 51.12 (a) Schematic of the coupling of an antiferromagnetic to a ferromagnetic film. (b) Geometry of the ferromagnetic film showing the induced easy-axis field, H_{ua} , the external magnetic fields H_{\parallel} and H_{\perp} and the magnetization of the film at an angle θ to the easy axis. (After [51.4])

the pinned film is achieved by coupling the ferromagnetic film to an antiferromagnetic film and the coupling results from the layer of spins in the antiferromagnetic film adjacent to the top layer of spins in the ferromagnetic film and is characterized by a coupling or exchange field of value H_{ua} . The geometry for the coupling is shown in Fig. 51.12a and the ferromagnetic film geometry with a magnetic field along the easy axis (H_{\parallel}) and the hard axis (H_{\perp}) as Fig. 51.12b. The coupling results in shifting the easy axis hysteresis curve (M_{\parallel}/M_s versus H_{\parallel}) of the ferromagnetic film by an amount H_{ua} , as shown in Fig. 51.13 [51.4]. The magnetization of the pinned film is held constant at $-M_s$ over the range of magnetic fields from large negative fields to $H_{\text{ua}} + H_k$. Note that the magnetization could be held at $+M_s$ by reversing the direction of the lower layer of spins in the antiferromagnetic film. The coupling field depends on the temperature and vanishes at the *blocking* temperature. The direction of the coupling is established during an annealing step by heating the structure above the blocking temperature, where the film is paramagnetic, in the presence of a magnetic field and then cooling the film below the blocking temperature. The choice of

Fig. 51.13 Magnetization curve with the magnetic field along the easy axis ($M_{||}/M_s$ versus $H_{||}$) for coupled antiferromagnetic and ferromagnetic films. (After [51.4])

antiferromagnetic films to be used in this application is extensive as shown in Table 51.2 [51.25–28]. The parameters listed in Table 51.2 are the strength of the coupling field (H_{ua}), the blocking temperature and the susceptibility of the antiferromagnetic and ferromagnetic films to corrosion. Corrosion is of concern in recording heads because of the mechanical lapping process used to form the surface on the bottom of the slider on which the air-bearing contour is etched [51.5]. One antiferromagnetic film with particularly favorable corrosion susceptibility is NiO. This film is typically used in a bottom spin valve in which the antiferromagnetic film is closest to the substrate. The other antiferromagnetic films are typically formed on top of the stack of films. Another advantageous film is the alloy of $\text{Pd}_{30}\text{Pt}_{20}\text{Mn}_{50}$ [51.28]. This ternary alloy has a favorable coupling strength H_{ua} but also a high blocking temperature (300 °C) and favorable

corrosion resistance. $\text{Pd}_{30}\text{Pt}_{20}\text{Mn}_{50}$ does require annealing the stack at 220–240 °C. The advantage of using an antiferromagnetic film for the pinning film instead of a permanent magnetic film is that the antiferromagnetic film does not itself respond to any external magnetic field since the film has a zero net magnetization.

Synthetic Antiferromagnets

The magnetic coupling between magnetic films closely spaced by certain nonmagnetic metal films oscillates between antiferromagnetic and ferromagnetic coupling. Using this fact, it is possible to design film structures that have a desired magnitude and sign of the magnetic coupling [51.29]. A schematic of a structure of films that exhibits this variable coupling is shown in Fig. 51.14a. Here the strong antiferromagnetic coupling of Co through Ru to soft $\text{Ni}_{80}\text{Co}_{20}$ is used to pin the magnetization in the adjacent $\text{Ni}_{80}\text{Co}_{20}$ film (F_I) to the direction opposite to the Co film and the thickness of the second layer of Ru can be adjusted to change the sign of the coupling between the two soft-magnetic films (F_I and F_{II}). Ruthenium is selected for the coupling film since it has a strong and oscillating coupling between Co, $\text{Ni}_{80}\text{Fe}_{20}$ and $\text{Ni}_{80}\text{Co}_{20}$. Ruthenium has the hexagonal close-packed (hcp) crystal structure with ($a = 0.271$ nm and $c = 0.428$ nm) while cobalt also has the hcp structure with ($a = 0.250$ nm and $c = 0.410$ nm) and therefore the two metals are expected to grow epitaxially. The experimental coupling constant (J_{12}) for this configuration of layers, where the soft-magnetic film is $\text{Ni}_{80}\text{Co}_{20}$, is shown as Fig. 51.14b. The units of the coupling constant are memu/cm^2 ($\times 10$ A in SI units) (coupling per unit of film area). The coupling constant can be either antiferromagnetic ($J_{12} < 0$) or ferromagnetic ($J_{12} > 0$) and can have a magnitude varying between +25 to -75 memu/cm^2 (+250 to -750 A). By varying the thickness of the Co layer it is possible to adjust the total magnetic field at the layer F_{II} to be zero.

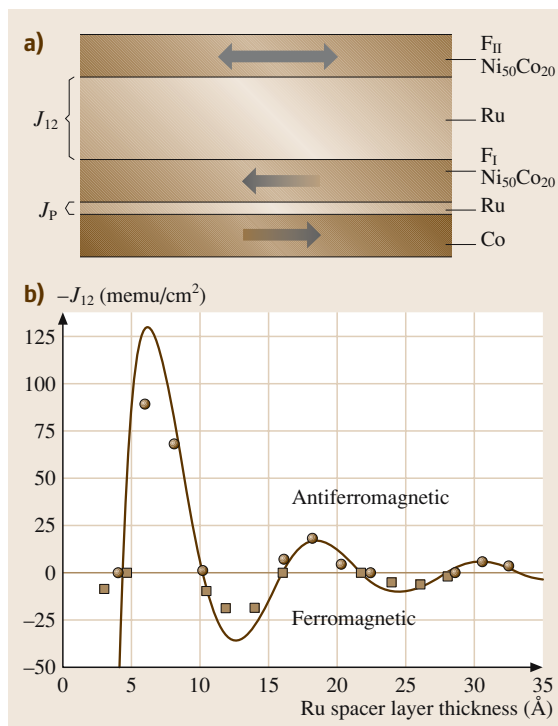

Fig. 51.14 (a) Geometry of ferromagnetic films coupled by thin layers of ruthenium. (b) Magnetic coupling constant per unit of film area between layers F_I and F_{II} of the films shown in (a) versus the thickness of the ruthenium layer. (After [51.29])

An overall spin valve consists of a sequence of thin films such as: MnFe 21 Å/Co 30 Å/Ru 7 Å/Co 30 Å/Cu 25 Å/Co 30 Å/Ni₈₀Fe₂₀ 28 Å, where the first four films (MnFe/Co/Ru/Co) form a *synthetic antiferromagnetic* film since the final Co film of these four films is pinned to a direction opposite to that for the first Co film. This Co film then acts as a pinned film in a spin valve together with the final three films (Cu, Co, and Ni₈₀Fe₂₀). The thickness of ruthenium listed in the sequence of films is optimum for antiferromagnetic coupling between the Co films. The last Co film is a nanolayer, which increases the magnetoresistive coefficient, as we have discussed [51.23]. The advantages of the synthetic antiferromagnet for pinning the pinned film compared with just an antiferromagnetic film (e.g., FeMn, NiO, NiMn or IrMn) are

1. the pinning coupling field is an order-of-magnitude larger, and

2. the magnetostatic coupling field from the pinned layer to the free layer is reduced. The magnetostatic coupling field is reduced since the two Co films in the synthetic antiferromagnet are antiferromagnetically coupled and hence their magnetostatic fields at the free film cancel. The synthetic antiferromagnet contributes to ensuring that the only magnetic field at the free film is that from the transitions in the recording medium.

One last requirement for the proper operation of the spin valve is that there is abutted on the two ends of the structure a permanent magnetic film referred to as the *hard bias* film (discussed in [51.4]). The permanent magnetic films are similar to the cobalt alloy magnetic films used for disk recording surfaces (to be discussed). The purpose of the hard bias is to reduce the presence of magnetic domains in the free film and to reduce Barkhausen jumps of the domain walls in the presence of the exter-

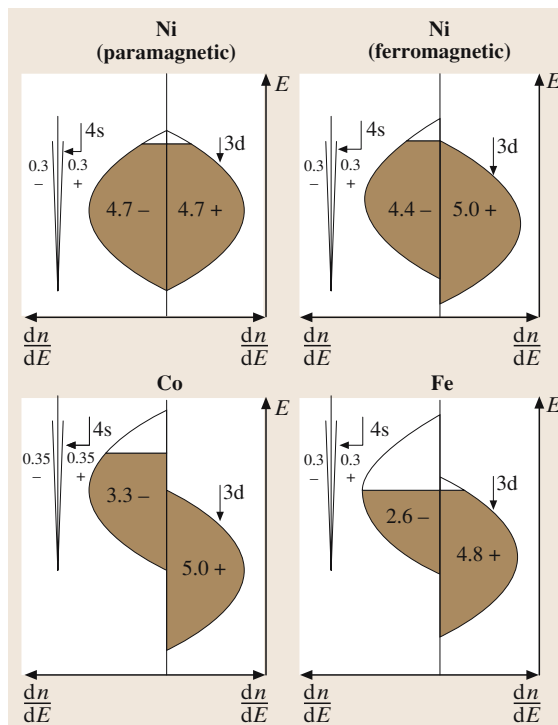

Fig. 51.15 Schematic of density of states curves for the ferromagnetic transition elements (Ni, Co and Fe). Both the 4s and 3d bands are shown. The magnetization of the elements is due to the difference between the spins in the spin-up and spin-down bands and the bands are full of electrons to the Fermi level (the shaded region). (After [51.30])

nal magnetic fields from the transitions in the recording medium.

The stack of films used in a spin valve has been discussed. The films used in Fig. 51.10, which we used to illustrate the GMR effect in a $\text{Co}_{90}\text{Fe}_{10}/\text{Ni}_{80}\text{Fe}_{20}$ free film, was: Ta (50 Å)/ $\text{Ni}_{80}\text{Fe}_{20}$ (60 Å)/ $\text{Co}_{90}\text{Fe}_{10}$ (55 Å)/Cu (variable)/ $\text{Co}_{90}\text{Fe}_{10}$ (55 Å)/FeMn (100 Å)/Ta (70 Å) [51.20]. In this case the antiferromagnetic film was FeMn (typically about 50%, 50%) and the Ta films are used to protect the rest of the stack.

Origin of GMR

The physical origin of the GMR effect lies in the differential scattering of electrons with spins in the same direction as the local magnetization (spin-up electrons) or opposite to this direction (spin-down electrons) at the interfaces and in the bulk part of the thin films comprising the GMR stack of films. The ferromagnetic transition elements (Fe, Co and Ni) have different 3d band structures, as shown in Fig. 51.15 [51.30] and discussed by [51.4]. This figure illustrates the energy of electrons in the two half-bands for spin-up and spin-down electrons versus the density of states $D(E)$ (number of states per unit energy per unit volume) in the 3d band for the ferromagnetic transition metals. The 4s bands are also shown. Electrons in the 4s bands make only a small contribution to the net spin but, because of the larger mobility (inversely proportional to the curvature of the bands), they are largely responsible for the current. The bands are filled to the Fermi energy at 0 K, and states above, but close to, the Fermi level are occupied at room temperature (illustrated by the shaded region in Fig. 51.15). The conductivity of a metal is given by

$$\sigma = \frac{1}{3} e^2 v_F^2 \tau D(E_F),$$

where e is the electron charge, v_F is the velocity of electrons at the Fermi energy, τ is the mean scattering time and $D(E_F)$ is the density of states at the Fermi energy [51.31]. If the mean scattering time (τ) is held constant then it is seen that the conductivity increases with the density of states at the Fermi energy; however, the scattering of the 4s electrons with a given spin is large when there are a large number of scattering centers and empty states with the same spin in the 3d band, i. e., the density of states at the Fermi energy $D(E_F)$ in the 3d band is large. In the ferromagnetic transition metals this is the largest effect and

$$\rho \propto D(E_F).$$

The scattering is due to spin–spin scattering, and spin–orbit scattering is believed to be small [51.32, 33]. The

Fig. 51.16 Density of states curves for the spin valve structure in the ferromagnetic spin configuration (*top figure*) and the antiferromagnetic spin configuration (*bottom figure*). The resistivities of the layers are shown on the bottom part of the figures. (After [51.30])

magnetic moment per atom can be deduced as the difference in the number of electrons/atom with spin-up (the majority) versus those with spin-down. For example, the magnetic moment per atom for iron is $4.8 - 2.6 = 2.2$ Bohr magnetons per atom. From Fig. 51.15 we conclude that the differential scattering will be large in cobalt since for this element the difference in the density of states at the Fermi level is large [approximately 8–10 to 1 [51.30]]. A schematic of the density of states versus energy for the three films comprising the spin valve structure from the two extreme cases of the orientation of the ferromagnetic films (ferromagnetic configuration and antiferromagnetic configuration) is shown in Fig. 51.16 [51.30, 34]. All films have the same Fermi energy. Mathon described the GMR effect by discussing the differential scattering of *holes* in the 3d bands, but by concentrating on the scattering of electrons from the 4s to the 3d band we can make the same conclusions [51.32, 34]. It is assumed that the mean free path for the electrons is large compared with the thickness of any layer in the superlattice. Consider the ferromagnetic configuration case (top of Fig. 51.16): here the majority electrons have spin-up and the scattering of 4s electrons is low in both ferromagnetic films since both have a low

Fig. 51.17 Distributions of local resistivities for the spin-up and spin-down electrons in the ferromagnetic and antiferromagnetic spin configurations. (After [51.30])

density of states at the Fermi level. The nonmagnetic film has a larger density of states and will scatter electrons regardless of the orientation of the ferromagnetic films, which is why this film must be thin. Now consider the antiferromagnetic configuration case in Fig. 51.16: from the density of states at the Fermi level in the three films it is seen that the scattering is large in the right-hand ferromagnetic film for the electrons leaving the left-hand ferromagnetic film with spin-up (top density-of-states curve), resulting in large resistivity for this class of electrons. Similarly, the scattering of spin-down electrons is large for the left-hand ferromagnetic film. The

Fig. 51.18 $\Delta R/R$ versus the thickness of the magnetic layer (M) for a nonmagnetic layer thickness (N) of 10 Å for a Co/Cu spin valve. (After [51.30])

Fig. 51.19 $\Delta R/R$ versus the thickness of the nonmagnetic layer (N) for a magnetic layer thickness (M) of 20 Å for a Co/Cu spin valve. (After [51.30])

resistivity for the spin-up and spin-down electrons for the three films [ferromagnetic (FM), nonmagnetic (NM) and ferromagnetic (FM)] in the ferromagnetic and antiferromagnetic orientation cases is shown as a schematic in Fig. 51.17 [51.30] where it is shown that the ferromagnetic orientation of the ferromagnetic films has a (relatively) low resistivity path for the spin-up electrons while the resistivity for the antiferromagnetic orientation of the ferromagnetic films is high for both spin-up and spin-down electrons.

The change in resistance of the spin valve structure can be analyzed in terms of the different resistivities for the ferromagnetic and antiferromagnetic orientation of the two ferromagnetic films shown in Fig. 51.16 [51.30]

$$\frac{\Delta R_{\max}}{R_0} = (\alpha - \beta)^2 / [4 (\alpha + t_{\text{nonmagnetic}}/t_{\text{magnetic}}) \times (\beta + t_{\text{nonmagnetic}}/t_{\text{magnetic}})] , \quad (51.12)$$

where

$$\alpha = \frac{\rho_M^H}{\rho_s}, \quad \beta = \frac{\rho_M^L}{\rho_s},$$

where $t_{\text{nonmagnetic}}$ is the thickness of the nonmagnetic film and t_{magnetic} is the thickness of the magnetic film.

Figure 51.18 shows the variation of $\Delta R_{\max}/R_0$ for $t_{\text{nonmagnetic}} = 10$ Å versus t_{magnetic} for assumed values of $\alpha = 8.0$ and $\beta = 1.0$, which is appropriate for a Co/Cu superlattice [51.30]. For thicknesses of the magnetic films beyond approximately 10 Å, the change in $\Delta R/R$ decreases. Figure 51.19 shows the variation of $\Delta R/R$ for $t_{\text{magnetic}} = 20$ Å versus $t_{\text{nonmagnetic}}$. The decrease in

$\Delta R/R$ is rapid with increasing thickness of the nonmagnetic layer. This combination of films is not used in spin valves since the cobalt film is not magnetically soft; the usual choice is Permalloy with a variety of nonmagnetic transition metals and the resulting $\Delta R/R$ is lower.

51.1.4 Longitudinal Recording Media

Magnetic recording media used in modern disk drives are all sputter-deposited thin films of cobalt alloys for high coercivity and media flux ($M_r \times \delta$). Coercivities of 4000–5000 Oe are used (2006) and are limited by the ability of the write head to record on the media. The alloys that have evolved are four- or five-element alloys of CoPtCrX , where X is Ta or B or both. A typical atomic concentration of the four-element media is $\text{Co}_{64}\text{Cr}_{24}\text{Pt}_8\text{B}_4$. It has been found necessary to form a microstructure in the magnetic film that consists of a phase of small magnetic grains isolated by a nonmagnetic phase. The isolation of the magnetic grains results in less exchange coupling between grains and reduced noise – as we will discuss. Chemical segregation of $\text{Co}_{100-x}\text{Cr}_x$ alloys forms a nonmagnetic phase (Cr-rich) and a magnetic phase (Co-rich) and the nonmagnetic phase forms at the grain boundaries. The microstructure is controlled by undercoats that promote grain growth with the axes of the grains in the plane of the film. Platinum results in higher crystalline anisotropy and boron promotes the formation of an amorphous alloy of CoCrB , which grows at the grain boundaries, further

reducing the exchange coupling. Figure 51.20 shows the microstructure for a magnetic recording surface, illustrating the separation of the grains by the amorphous CoCr phase and, in the lower image, the c -axis stacking of the hcp grains [51.35]. In five-element alloys [CoCrPtBTa], Ta assists the segregation of Cr at the grain boundaries [51.36]. Some recording media use as many as three magnetic layers with the saturation magnetization increasing towards the read head, so that the average saturation magnetization is reduced while the magnetization nearest to the read head is increased. The layer of films comprising a recording layer at the areal densities for a 130-Gb/in² demonstration were: NiP-plated aluminium substrate with mechanical texturing in the data-recording zone/Cr seed layer/a CrMoX (X = grain-boundary segregation-enhancement element) underlayer/a CoCrT intermediate layer/two ferromagnetic layers (one with high Cr/low B concentration and the second with low Cr/high B concentration) and a double-layer amorphous carbon overcoat [51.37]. The substrate used for the samples in Fig. 51.20 was glass. Glass substrates have several advantages over aluminium with electroless Ni(P) (for hardness) substrates, including increased stiffness, which leads to reduced flutter, increased hardness and reduced susceptibility to corrosion. However, aluminium substrates continue to be used in nonportable applications because of reduced cost. The amorphous carbon is required to protect the magnetic film and to give a mechanically rigid surface on which the slider can fly at less than 25 nm.

Fig. 51.20a,b Plan-view electron microscope images [the upper image (a) is lower resolution and the lower (b) is higher resolution] of the CoPtCrB magnetic alloy layer used in the 35-Gb/in² demonstration by IBM. The amorphous grain boundaries are seen as white and the c -axis stacking of the hcp grains can be seen within the grains in the higher-resolution image. (After [51.35].) The images were taken by Kai Tsang of IBM

Media Noise

In modern digital recording systems the dominant noise voltage which appears simultaneously with the desired read signal at the terminals of the read head is that from the recording media, assuming that the resistance from the read head is not excessive. Noise in the read channel is caused by random variations in the location of the recorded transitions. Transitions are not straight across the recorded track, as we assumed in our discussion of the transition parameter, but instead form zig-zag patterns in order to reduce the large demagnetizing field and demagnetizing energy associated with the longitudinal transition (discussed in [51.4]). Transitions also tend to follow the grain boundaries in the polycrystalline media. To achieve low media noise, it is required to have a small grain size so that the random nature of the grains is averaged over the width of the read head (the track width). An analysis of the signal-to-noise ratio, defined as the base-to-peak signal voltage amplitude (S_0) over the media noise voltage amplitude (N) has been published [51.24]

$$\left(\frac{S_0}{N}\right)^2 = 0.31 \left(\frac{B}{a}\right)^2 \left(\frac{PW_{50}}{B}\right) \frac{W_r}{W_c}, \tag{51.13}$$

- W_r : width of read head,
- PW_{50} : width of the read pulse at 50% of the peak amplitude,
- W_c : cross-track correlation width, which has been approximated as the grain or cluster size of the recording media. The grain size is a distribution and W_c is the mean of the distribution,
- a : transition parameter discussed above,
- B : length between bits.

For a reliable low error rate the value of $20\log S_0/N$ is required to be above 26–27 dB and this has required an increasingly smaller grain size as the width of the read head has decreased, resulting in higher track densities. For a 10-Gb/in² system the value of W_r was 0.505 μm and the required mean of the grain size was 12 nm [51.38]. The ratio B/a has been ≈ 3 to avoid severe distortion of the transition across the track, referred to as percolation (discussed in [51.4]) and the ratio PW_{50}/B has been in the region 2.5–2.8 for the type of detection channels used in present disk drives [partial response maximum likelihood (PRML)]. Therefore, to maintain constant S_0/N the ratio of the track width to the grain size must be kept constant and, with the decreased track width, the grain size must decrease in proportion.

Increased areal density has required decreased mean grain size but, equally important, tighter distributions

Table 51.3 Comparison of 20- and 80-GB/platter disk characteristics (after [51.17])

	20 GB/ 90 mm disk	80 GB/ 90 mm disk
H_c (Oe)	2700	4200
$M_r\delta$ (memu/cm ²)	0.46	0.32
Average grain size (nm)	10.8	9.1
Distribution sigma	0.41	0.24
Amplitude decay rate (%/decade)	0.7	0.4

of grain size. The distributions are closely matched by log-normal distributions of the form

$$y = \frac{1}{\sigma_Z \sqrt{2\pi}} \exp\left(-\frac{(Z - \bar{Z})^2}{2\sigma_Z^2}\right), \tag{51.14}$$

where Z is the log₁₀ value of the grain diameter, \bar{Z} is the mean value of Z and σ_Z is the standard deviation of Z . Grain size distributions are measured on foils by tunneling electron microscopy (TEM). Figure 51.20 showed the microstructure of a typical recording surface, emphasizing the segregation of the grains by the nonmagnetic constituents of the alloy. The distribution of the grain sizes in recording media for 20 GB/platter (counting both sides of the platter) and the higher density 80 GB/platter are shown in Table 51.3 [51.17]. Both the mean and standard deviation for the 80 GB/platter are reduced from those of the 20 GB/platter media. We will discuss the decay rates shown in Table 51.3 in the next section. The trend in the mean grain size and grains

Fig. 51.21 Grain size and grains/bit for sputtered cobalt alloys as a function of areal density in Gb/in². (After [51.17])

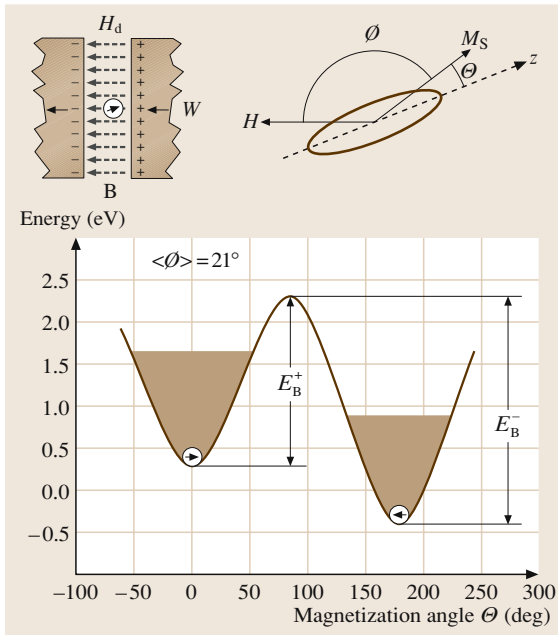

Fig. 51.22 Calculated energy of an isolated single-domain particle at the center of an 80-nm-long dibit transition. The properties of the particle are listed in Table 51.4. The ratio of the barrier height to thermal energy is 43 (see text) and the height $43 k_B T$ is shown shaded. There is margin between the top of the shaded region and E_B^+ and the particle is stable for the time t_x of 10 y. (After [51.39])

per bit for recording films versus areal density is shown in Fig. 51.21 [51.17]. A serious problem with this trend is the fact that the ratio of magnetic to nonmagnetic volume in the film is decreasing faster than the average grain size, which results in the number of grains per bit decreasing faster than the average grain size. The price to be paid for the increasingly small grain size is the stability of the recorded data over time as we discuss in the

next section. To investigate how far the areal density can be extended with longitudinal recording use has been made of the signal-to-noise ratio calculation to see if an areal density of 200 Gb/in² is feasible. To ensure that the signal-to-noise ratio does not degrade when extending the areal density from 60 to 200 Gb/in², it is required that: (a) the transition parameter be reduced from 12.8 to 6.2 nm, to achieve which the coercive field (H_c) must be increased from 4000 to 5000 Oe, and (b) the product of the magnetization and thickness ($M_r \delta$) be reduced from 0.32 to 0.2 memu/cm³. In addition, the head-medium spacing must be reduced from 30 to 15 nm [51.17].

Superparamagnetic Effect

To maintain the growth in areal density as shown in Fig. 51.1, it is necessary to reduce the physical dimensions of the recording-system components — and, to maintain the signal-to-noise ratio at levels required for satisfactory error rates, this includes reducing the mean grain size of the recording media. However, at some grain size the thermally driven fluctuations of the orientation of the magnetization in the isolated grains result in increased probability of the magnetization being switched from the desired orientation, as initially recorded, to the opposite direction. This instability of the magnetization is the *superparamagnetic effect*. The magnetic energy in an isolated grain is $K_u V$, where K_u is the uniaxial anisotropy consisting of crystalline, magnetostriction and shape contributions and V is the volume of the particle or grain with diameter D [$\pi(D/2)^2 \delta$]. Thermal energy supplied from the environment to the particle is $k_B T$, where k_B is the Boltzmann constant (0.8619×10^{-4} eV/K). An analysis of the superparamagnetic effect using an isolated small single-domain asymmetrical particle is summarized in Fig. 51.22 [51.39]. Here, the magnetic particle is assumed to be in the center of two transitions and the energy contour results from an analysis using only

Table 51.4 Energy of single-domain particle in magnetic field of two transitions (after [51.39])

Parameter	Value
B (dibit length)	80 nm
K_u (particle anisotropy energy, consisting of shape and crystalline anisotropy contributions)	1.5×10^6 erg/cm ³ (1.5×10^5 J/m ³)
$M_r \delta$	0.39 memu/cm ² (3.9 mA)
M_S	375 emu/cm ³ (375×10^3 A/m)
D (grain or particle diameter)	15 nm
δ (media thickness)	13 nm
V (grain or particle volume)	$\pi \times (D/2)^2 \times \delta$
H_d (demagnetizing field between transitions)	780 Oe (62 kA/m)
$\langle \phi \rangle$ (mean angle of field with respect to grain or particle axis)	21°

shape and crystalline anisotropy (combined into K_u) and magnetostatic energy terms.

$$E(\theta, \phi) = K_u V \sin^2 \theta + H M_s \cos(\theta - \phi) \quad (51.15)$$

It is assumed in Fig. 51.22 that the angle ϕ has a mean value $\langle \phi \rangle = 21^\circ$. The energy contour shown in Fig. 51.22 results from the application of (51.15) with the parameters listed in Table 51.4. The energy required to switch the particle from the initially magnetized direction is shown as E_B^+ . In the absence of an external or demagnetizing field, the energy barrier is

$$E_B^+ = K_u V.$$

With a demagnetizing field (H_d) the switching field is reduced since the field is in the direction of the switched magnetization

$$E_B^+ = K_u V \left(1 - \frac{|H_d|}{H_0} \right)^{1/2} \quad (51.16)$$

With a random two-dimensional (2-D) system $H_0 = 2K_u/M_s$. The magnetization of the particle will switch when $H_0 = H_d$. When the magnetization of the particle is switched, the new energy barrier is E_B^- and is increased in depth since the demagnetizing field is now in the same direction as the magnetization. Using the set of parameters listed in Table 51.4, the depth of E_B^+ [with a demagnetizing field of 780 Oe (62 kA/m)] is approximately 1.9 eV.

The time constant for the thermally driven switching of the magnetic particle in the presence of a magnetic field, which in the case under consideration is the demagnetizing field acting on the magnetic particle, can be found using an Arrhenius–Néel model

$$\tau = \tau_0 \exp \left(\frac{-E_B^+(H)}{k_B T} \right),$$

where $\tau_0 = 1/f_0$ and f_0 is an *attempt frequency*, usually taken as $\approx 10^9$ Hz [51.39]. The energy barrier depends on the thermal energy and the fraction x ($0 < x < 1$) of the retained magnetization and the storage time t_x

$$E_B^+(H) = \ln \left(\frac{t_x f_0}{|\ln x|} \right) k_B T, \quad (51.17)$$

$$t_x = |\ln x| (\tau_0) \exp \left(\frac{E_B^+(H)}{k_B T} \right).$$

As an example, if the required storage time is $\approx 10^8$ s (10y) and the percentage loss of data amplitude is 5%, then $x = 0.95$ and $|\ln 0.95| = 0.05$ and

$$\frac{E_B(H)}{k_B T} \cong 43.$$

Fig. 51.23 Signal loss versus time at room temperature and 300 k flux changes per inch for three magnetic recording surfaces: The first two (from the top) are SFM and AFC media with layer thicknesses of: [12 nm/0.7 nm/4 nm] (open square), [12 nm/1.4 nm/4 nm] (open circle). The lower curve is for a 12-nm single layer (solid diamond). (After [51.40])

The thermal energy $k_B T$ at 350 K (the assumed operating temperature of a typical disk drive) is 0.03 eV, $43 \times k_B T \approx 1.25$ eV and the shaded region in Fig. 51.22 has this energy level. Since there is some margin between the thermally driven contribution to switching and the top of the barrier, the particle is stable (over the 10-year period). However, for smaller volumes (V) the value of E_B^+ decreases and the particle could become unstable. For example, if the thickness of the recording media is reduced from that assumed in Fig. 51.22 (13 nm) to 6 nm, the value of E_B^+ is reduced to ≈ 0.9 eV and the thermal energy would easily switch the particle.

A dramatic loss of data over time is observed with recording media with media flux ($M_r \times \delta$) less than about 0.25 memu/cm². Figure 51.23 shows amplitude loss of recorded data for three different media at a linear density of 300 k flux changes per inch at room temperature [51.40]. The three media are: a single-layer of CoCrPtB (lowest curve with a thickness of 12 nm); and two recording surfaces we will discuss in the next section. The signal decay rate R is defined as

$$R(H_d, T) = 100 \frac{\frac{A(t)}{A(t_0)} - 1}{\log(t/t_0)}, \quad (51.18)$$

where the signal amplitude of a square-wave pattern is $A(t)$. With $t_0 = 1$ s, the decay rate per decade for the media shown as the lower curve in Fig. 51.23 is

found to be -7.19% . The decay rate for the other media will be discussed in the next section. The decay rates for the two recording films shown in Table 51.3 are $-0.7\%/decade$ and $-0.4\%/decade$ for the 20 GB/platter and 80 GB/platter media, respectively. In a conventional disk recording system this superparamagnetic effect was judged to limit the areal density to somewhere in the range $36\text{--}100\text{ Gb/in}^2$ (reviewed in [51.39]). The superparamagnetic effect and the requirement for low media noise result in recording-system designers being caught in two inconsistent requirements: first, a small grain size for the recording media is required for adequate signal-to-noise ratio, so that the number of grains per bit remains constant (51.13), and second, a large grain size is required for small data loss over time because of the superparamagnetic effect [(51.16) and (51.17)]. The requirement to reduce the thickness of the recording media can be deduced from the need for low values of $M_r\delta$ for short transition lengths (51.5). The approach of increasing the anisotropy of the grains to increase $K_u V$ to resolving the superparamagnetic effect is limited by the ability of write heads to record on the media with the resulting increased media coercivity. The present values of areal density are approaching this limit. However, as can be seen from Table 51.3, the decay rates observed with the smaller grain size–higher density media is actually smaller than that for the larger grain size–lower density media. A possible explanation is that the $K_u V$ values for the smaller grains are higher than for the larger grains [51.17]. In the next section we discuss a novel approach that has extended the progression in areal density.

Antiferromagnetically Coupled (AFC) or Synthetic Ferrimagnetic (SFM) Media

The invention of a new form of recording media which has decreased the impact of the superparamagnetic effect was accomplished simultaneously by teams of researchers at the Fujitsu and IBM Almaden Research Laboratories [51.41, 42]. The new form of recording media consists of two ferromagnetic layers coupled by a thin layer of ruthenium [antiferromagnetically coupled (AFC) or synthetic ferromagnetic media (SFM)], which results in an antiferromagnetic coupling of the two films, similar to that used in the spin valve for a synthetic antiferromagnet. In order for the coupling between the two ferromagnetic layers to be antiferromagnetic, the thickness of the ruthenium layer, referred to by IBM as “pixie dust”, is required to be approximately 0.6 nm [51.42]. A schematic of the antiferromagnetic coupled media and the resulting hysteresis curve is

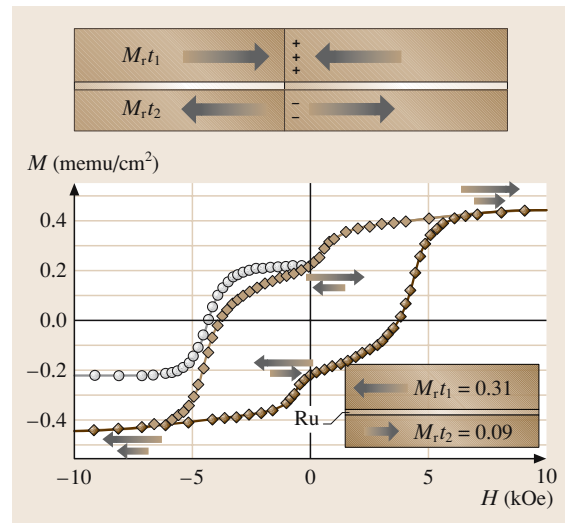

Fig. 51.24 (top) Schematic of the antiferromagnetically coupled (SFM or AFC) media showing the two ferromagnetic layers coupled by a thin layer of ruthenium (“pixie dust”) and with a single magnetic transition for which the magnetizations in the two layers are oppositely directed. (bottom) Magnetic hysteresis curve for the SFM or AFC media with remanent thickness products for the two ferromagnetic layers shown in the inset and measured at 350 K. The filled triangles are the major hysteresis curve and the filled circles are the remanence hysteresis curve. The arrows show the directions of the magnetization in the two films. (After [51.40])

shown as Fig. 51.24 [51.40]. The sharp reduction in the remanent magnetization at $\approx 80\text{ Oe}$ is due to the switching of the thinner lower layer ($M_r t_2$) and the lowered value of the remanence is advantageous for reduced transition noise and transition length. The curve with solid circles is a remanence hysteresis curve measured by subjecting the sample to a negative reversing field and then increasing the field in a positive direction to zero and plotting the remanent magnetization. This measurement is an attempt to simulate what happens when a recording medium leaves the vicinity of the recording head. By analyzing the read pulse from the transition in the upper layer combined with the read pulse from the transition with reversed sign from the lower layer (the layers are antiferromagnetically coupled), it can be shown that no degradation of the resolution (PW_{50}) of the system results from having two as opposed to one recording layer [51.42]. The advantage of the AFC or SFM configuration is that the medium is in fact thicker than would be required for the given recording density using a single

layer and hence is less susceptible to the superparamagnetic effect (51.17). The effective volume is bounded by

$$K_uV_1 < K_uV_{\text{eff}} < K_uV_1 + K_uV_2$$

and with tight coupling and alignment of the axes of the grains the upper limit is approached. The effective remanent magnetization \times thickness product is close to

$$M_{\text{r}}t_1 - M_{\text{r}}t_2$$

and this reduces the pulse width over that a single-layer recording medium (51.10).

Because of the antiferromagnetic coupling, an exchange magnetic field $H_{\text{ex},2}$ acts on the lower magnetic film

$$H_{\text{ex},2} = \frac{J_{\text{ex},2}}{M_2t_2}$$

and a typical value for the antiferromagnetic exchange constant $J_{\text{ex},2}$ is 0.06 erg/cm³ (6 mJ/m³) [51.44]. For the magnetization of the lower layer to assume the opposite direction to that of the top layer before the field H is reduced to zero, it is required that $H_{\text{ex},2} > H_{\text{c}2}$. The antiferromagnetic exchange constant can be increased by adding a thin layers of cobalt or cobalt alloys known as E layers to both sides of the ruthenium layer [51.43]. The increase in the antiferromagnetic exchange constant is rapid with thickness of the E layers and we show in Table 51.5 a listing of J_{ex} for several E layers [51.43]. The largest increase in J_{ex} is with cobalt, but this material suffers from significant degradation on overwrite and poor signal-to-noise ratio compared with cobalt alloys.

To illustrate that the AFM or SFM media configuration actually results in reduced amplitude loss over time, we show in Fig. 51.23 the amplitude loss with two SFM media: 12/0.7/4 (open squares) and 12/1.4/4 (open circles), where the numbers are the thickness of the three layers in nm and the value of $E_{\text{B}}/k_{\text{B}}T$ is 38 [51.40]. The signal decay rate is -4.14% per decade for the top curve (open squares) and -6.45% per decade for the middle curve (open circles) [51.40]. The coupling between the

two magnetic films is antiferromagnetic for the top curve and ferromagnetic for the middle curve and the lower curve is a single magnetic layer. The AFM or SFM media clearly reduces the decay rate. The improvement is even more significant with a larger value for $E_{\text{B}}/k_{\text{B}}T$ and values of R less than 1%/decade with $M_{\text{r}}t$ values lower than 0.2 memu/cm² have been reported by IBM researchers using static magnetization measurements with a reversing magnetic field to mimic the demagnetizing field [51.42]. AFM media are being used in IBM portable disk-drive applications [51.45]. Areal densities larger than 100 Gb/in² have been reported with longitudinal recording using AFM media [51.46]. The magnetic recording layers were alloys of CoCrPtB with an average grain size of 9.4 nm. The write head was trimmed on the air-bearing surface to the final track width using a focused ion beam and the track density was 149 ktracks/in and the bit density was 720 kbits/in [51.46].

The data shown in Table 51.3 also shows that it is possible to achieve low decay rates with single recording layers [51.17]. Analysis comparing SAF and single-layer media has shown that the single-layer media is preferred unless the media flux drops below about 0.25 memu/cm² with H_{c} values constrained below 4300 Oe. If recording heads are able to record with adequate overwrite on media with coercivity greater 4300 Oe, then the single-layer media is preferred [51.47].

Dynamic Coercivity

Another manifestation of thermal effects on magnetic properties is a change in coercivity with switching time. With long periods of time the probability that a particle will switch is increased by thermal excitation and with short periods this probability is decreased – leading to a change in the coercivity of the particle. An experimental study of this effect was done on a test stand in which a stationary write head is driven by a current pulse of variable duration over a previously magnetically saturated recording medium. The current pulse records two transitions (a dibt). The width of each transition is essentially the gap of the write head and the length of

Table 51.5 Comparison of materials for E layers: J_{ex} values and degradation in overwrite and signal to media noise (after [51.43])

Material for E layers (all 1 nm thick)	Co	Co–Cr	Co–Cr–X
J_{ex} (erg/cm ²)	0.73	0.59	0.24
Degradation in overwrite (dB) with respect to SFM media without E layers (negative values indicate improved overwrite)	10	≈ 3	≈ -6
Degradation in S/N _m (dB) with respect to SFM media without E layers	≈ 4.5	≈ 1.6	≈ 1.5

Fig. 51.25 Dynamic coercivity $H_{CR}(t)$ for a series of $\text{Co}_{64}\text{Pt}_{14}\text{Cr}_{22}$ films with variable thickness. (After [51.39])

the reversed magnetization region varies with the pulse width (t_p). The dibit is read with a magnetoresistive sensor moved across the recorded transitions resulting in a dibit pulse. By measuring the amplitude of the dibit signal as a function of the pulse width and varying the magnitude of the reverse field and measuring $H_{\text{head}}(I)$ it is possible to deduce the remanent coercivity (H_{CR}) as a function of t_p . The resulting curves of $H_{CR}/H_{CR}(1 \text{ ns})$ are shown in Fig. 51.25 [51.39]. The experimental slopes C increase as the thickness decreases. The inverse slope parameter is given by

$$\frac{1}{C} \cong \frac{K_u V}{k_B T},$$

which is the superparamagnetic stability parameter discussed above and it is observed that, even with a stability factor larger than 51, for which the superparamagnetic region is avoided, the coercivity increases significantly for short switching times. This is the actual coercivity that must be exceeded by the write-head magnetic fields to switch a recording film.

51.1.5 Perpendicular Recording

The technology that is now starting to supplant longitudinal recording is perpendicular recording. Perpendicular recording offers a way out of the conundrum caused by the need for thinner recording media for improvements in recording density and the need for larger particles to reduce the impact of superparamagnetism. In perpendicular recording the magnetization in the recording media is held perpendicular to the surface

Fig. 51.26 Schematic of a perpendicular recording system. (After [51.4])

of the recording media by a perpendicular anisotropy large enough to overcome the large demagnetizing field with this orientation of the magnetization. A schematic of a perpendicular recording system including a probe write element and a magnetically soft underlayer (SUL) is shown as Fig. 51.26. It is also possible to have a perpendicular recording system with a ring write head and a single-layer media, but this approach has not been developed. In contrast to longitudinal magnetic recording the SUL is required for a low-reluctance path for the magnetic flux generated by the coil on the write element. One advantage of perpendicular recording is that the magnetic field for recording is larger than that for longitudinal recording since the magnetic field from the write pole is in the gap of the write head, in contrast to longitudinal recording where the field leaks from the write gap. A schematic of the total geometry for longitudinal and perpendicular recording is shown in Fig. 51.27 [51.1]. Reading for perpendicular recording is accomplished with a GMR sensor as with longitudinal recording. The major difference in the write head is that it uses a single pole to generate the perpendicular magnetic field with a wider (to reduce the reluctance) return pole. The write head for perpendicular recording is imaged in the SUL and this results in an increase in the strength of the magnetic field by approximately a factor of two. In addition, due to imaging effects, the effective number of turns on the write head is doubled for perpendicular recording. It is important for perpendicular recording that the magnetization of the magnetic material for the SUL be larger than that for the pole of the write head [51.48]. This is the case to prevent the SUL from saturating before the pole tip saturates, resulting in a decrease in the gradient of the head field, which would result in an

Fig. 51.27 Schematic of longitudinal and perpendicular recording systems. (After [51.1])

increased transition length (to be discussed). A large magnetic field and gradient of magnetic field from the write head can record media with a larger coercive field than for longitudinal recording, which results in a reduced transition length. Perpendicular-recording media can be made thicker than for longitudinal media for the same areal density. The media thermal stability factor ($\frac{K_u V}{k_B T}$) is increased both by an increase in K_u by virtue of the increased coercive field but also by the increase in the volume (V) with the thicker media. Reading of the magnetic transitions with perpendicular recording is done with a spin valve head as with longitudinal

recording – the difference being that with perpendicular recording the response is a step instead of a pulse (to be discussed).

A significant recent development for perpendicular write heads is the addition of a trailing-edge shield to the head that results in an improvement in the concentration of the writing flux and an increase in the gradient of the head field (dH_y/dx), which reduces the transition length [51.49,50]. A schematic of a write head with a trailing-edge shield is shown in Fig. 51.28 [51.51]. The shield connects to the larger return structure for the head shown in Fig. 51.27. The particular geometry

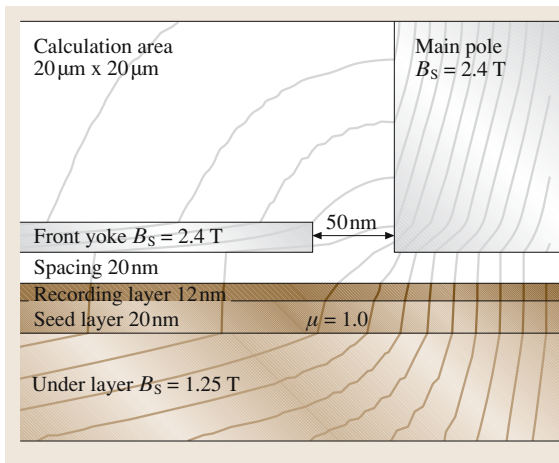

Fig. 51.28 Schematic of a perpendicular recording head including the main pole and the front yoke or trailing-edge shield. (After [51.51])

and saturation magnetization of the main pole and the *front yoke* or trailing-edge shield were used in a two-dimensional finite element model to calculate the head fields and shape of the recorded transition [51.51]. Results of the simulation of transition shape are shown in Fig. 51.29, where it is seen that the recorded transition is considerably sharper with the head with the front

Fig. 51.29 Magnetic transitions in perpendicular recording with and without the front yoke or trailing-edge shield. (After [51.51])

yoke compared with the head without the shield, particularly with the higher coercivity media ($H_c = 8000$ Oe). The perpendicular magnetic field has the amplitude reduced to one-half at a distance of $0.8d$ with the shield and $1.3d$ without the shield (assuming that the spacing of the shield is spaced by a distance d from the main pole) [51.50]. The shield shunts some of the write flux, reducing the amplitude of the write field, so it is important to keep the height of the shield short. Another advantage of the trailing-edge shield is that a horizontal component of the field is added. This field reduces the field for switching since, if the angle of the field is θ , the switching field is

$$H_{\text{switch}} = \frac{H_k}{[(\cos \theta)^{2/3} + (\sin \theta)^{2/3}]^{3/2}},$$

where H_k is the anisotropy field of the perpendicular medium. The denominator of this equation is always larger than one and hence the switching field is reduced for angles θ larger than zero degrees. Note that this equation is the switching asteroid equation used to explain the operation of the MRAM (to be discussed).

A significant advantage of perpendicular as compared with longitudinal recording is the narrower off-track read profile as shown in Fig. 51.30 [51.50]. This improvement in read profile leads directly to increased track density in disk drives where there is significant skew of the head with respect to the track center line. Head skew results from the fact that present disk drives

Fig. 51.30 Cross-track profile of the signal with perpendicular and longitudinal recording. (After [51.50])

Fig. 51.31 Magnetization and perpendicular anisotropy for a perpendicular recording media. (After [51.4])

use rotary actuators and the angle of the written transition with respect to the track center line varies as the actuator is rotated across the disk, being largest at the inside and outside diameters. With head skew it is possible for the write element of the head to be placed over the guard band or adjacent track of a selected track, resulting in unwanted recording in these areas. This problem is reduced by using trapezoidal poles [51.52]. Shields can be added to the side of the head to reduce this erasure of adjacent track information; however, the processing of such shields is complex.

Media for Perpendicular Recording

The magnetization and anisotropy in a perpendicular recording film is shown as Fig. 51.31. The energy of the magnetization in the presence of the demagnetizing, anisotropy and magnetostatic energies (cgs units) is

$$E = \frac{1}{2} 4\pi M_s^2 \cos^2 \theta + K_u \sin^2 \theta - H_{\text{ext}} M_s \cos \theta, \quad (51.19)$$

where the demagnetizing factor for a thin film magnetized normal to the surface is 4π . The equilibrium angle is given by the solution to

$$\frac{dE}{d\theta} = \frac{4\pi}{2} (-2 \cos \theta \sin \theta) M_s^2 + 2K_u \sin \theta \cos \theta + H_{\text{ext}} M_s \sin \theta = 0. \quad (51.20)$$

For stability

$$\frac{d^2 E}{d\theta^2} = -4\pi (\cos^2 \theta - \sin^2 \theta) M_s^2 + 2K_u (\cos^2 \theta - \sin^2 \theta) + H_{\text{ext}} M_s \cos \theta > 0. \quad (51.21)$$

The solution is $\sin \theta = 0$ ($\theta = 0^\circ$ or 180°) and the stability condition for $H_{\text{ext}} = 0$ results in

$$K_u > 2\pi M_s^2. \quad (51.22)$$

Alloys under consideration for perpendicular recording include those listed in Table 51.6 [51.53] and Table 51.7. A review of work on perpendicular recording media was published [51.54]. It is observed from this table that these candidate materials satisfy the condition (51.22). The critical magnetic field below which the $\theta = 0^\circ$ solution is no longer stable is given by the solution to (51.21) with $H_{\text{ext}} \neq 0$, resulting in

$$H_{\text{e,crit}}(\theta = 0^\circ) = -\frac{(2K_u - 4\pi M_s^2)}{M_s},$$

$$H_{\text{e,crit}}(\theta = 180^\circ) = \frac{(2K_u - 4\pi M_s^2)}{M_s}. \quad (51.23)$$

The solution to (51.21) with $\sin \theta$ factored out is

$$-4\pi M_s^2 \cos \theta + 2K_u \cos \theta + H_{\text{ext}} M_s = 0,$$

$$H_{\text{ext}} = \cos \theta (4\pi M_s - 2K_u/M_s),$$

$$M_{\perp}/M_s = \cos \theta,$$

$$M_{\perp}/M_s = \frac{H_{\text{ext}}}{(4\pi M_s - 2K_u/M_s)}. \quad (51.24)$$

This solution applies when the magnetization curve is not saturated. $H_{\text{e,crit}}$ is not the same as the coercive field where $M(H_{\text{ext}}) = 0$. The coercive field is found from (51.20) by recognizing that the magnetic field $H_{\text{ext}} = -|H_{\text{e,crit}}| - H'$, where H' is measured from $-|H_{\text{e,crit}}|$. The coercive field is then

$$H_c = -2|H_{\text{e,crit}}|.$$

The result for a Co–Cr–Pt alloy (Table 51.7) with the following parameters: $K_u = 1.45 \times 10^6$ erg/cm³, $M_s = 280$ emu/cm³ is as follows

$$H_{\text{e,crit}}(\theta = 0^\circ) = -\frac{(2K_u - 4\pi M_s^2)}{M_s},$$

$$H_{\text{e,crit}}(\theta = 0^\circ) = -\frac{(2 \times 1.45 \times 10^6 - 4\pi 280^2)}{280},$$

$$H_{\text{e,crit}}(\theta = 0^\circ) = -6838 \text{ Oe},$$

$$H_{\text{e,crit}}(\theta = 180^\circ) = 6838 \text{ Oe}.$$

Table 51.6 Magnetic properties of selected materials for perpendicular recording (data from [51.53])

The magnetization curve for the second quadrant is:

$$M_{\perp}/M_s = \frac{H_{\text{ext}}}{(4\pi M_s - 2K_u/M_s)},$$

**Fig. 51.32** Hysteresis curve for Co–Cr–Pt perpendicular recording media using the analysis in the text

$$M_{\perp}/M_s = \frac{(H_{\text{ext}} + 2 \times |H_{e,\text{crit}}|)}{|H_{e,\text{crit}}|},$$

$$H_c = -2 \times |H_{e,\text{crit}}| = -13.67 \text{ kOe}.$$

The magnetization curve for the fourth quadrant is:

$$M_{\perp}/M_s = \frac{(H_{\text{ext}} - |H_{e,\text{crit}}|)}{|H_{e,\text{crit}}|} - 1.$$

The magnetization curve is shown in Fig. 51.32 and exhibits the desired large coercivity but the curve is sheared due to the large demagnetizing field.

In general, the magnetic hysteresis curve (M versus H_{ext}) for the recording medium is as illustrated in Fig. 51.33 [51.53]. Here the slope parameter (α) characterizes the slope of the magnetization curve at $H = -H_c$,

$$\alpha = 4\pi \left(\frac{dM}{dH} \right)_{H=-H_c}. \quad (51.25)$$

Finite values of α result from variations in the direction of the perpendicular magnetization, dispersion in the

Fig. 51.33 Hysteresis curve with demagnetizing field ($4\pi M_s/\alpha$) and a reduced demagnetizing factor N_d for a perpendicular recording film with loop slope parameter α . (After [51.53])

perpendicular anisotropy and variations in the exchange coupling between grains and clusters in the media. The effective demagnetizing field is reduced from $4\pi M$ to $4\pi M/\alpha$. This reduction in demagnetizing field results from the formation of a rectangular checkerboard pattern of domains with high-density linear recording and high track densities [51.53]. The effective anisotropy energy, which assists in overcoming the thermal energy and the superparamagnetic limit, is given in terms of the nucleation field (H'_n), at which field the magnetization just starts to reverse, by

$$K_{\text{eff}} = H'_n M_s / 2.$$

For high areal density an estimate of the reduced demagnetizing factor is

$$N'_d = 0.5 \times 4\pi M_s$$

and the increase in the nucleation field H_n is

$$H'_n = H_n + \frac{4\pi M_s}{2}.$$

For high-density recording large values for α and H_c are required; however, the value of H_c is limited by the ability of the pole head to generate magnetic fields equal to or greater than approximately $1.5 \times H_c$, the condition that ensures adequate overwrite.

The transition parameter (a) for perpendicular recording can be estimated using the same write-slope

Table 51.8 Parameters for evaluating transition parameters for longitudinal and perpendicular recording

Parameter	a_L	a_P
d (nm)	26	26
t (nm)	—	50
u (nm)	—	0
S^*	0.95	0.98
M_r (emu/cm ³)	200	200
δ (nm)	14	—
Q	0.6	0.6
$H_{c,\text{max}}$ (Oe)	3500	8000

criteria discussed for longitudinal recording [51.68]. Here,

$$\frac{dM}{dx} = \frac{dM}{dH} \left(\frac{dH_{\text{head}}}{dx} + \frac{dH_{\text{demagnetizing}}}{dx} \right). \quad (51.26)$$

This equation is solved by assuming an arctangent transition shape and denoting the slope of the head field by $\frac{dH_{\text{head}}}{dx} = QH_c/s$, where s is the total spacing of the write pole tip to the top of the SUL, consisting of the physical spacing (d), the thickness of the recording media (δ) and the spacing between the SUL and the magnetic recording film (u). Using the demagnetizing field for a perpendicular transition [51.69]

$$a = a_1 + \sqrt{\left(a_1^2 + \frac{(1-S^*)\delta s}{\pi Q} \right)},$$

$$a_1 = \frac{4M_r s}{QH_c} + \frac{s(1-S^*)}{\pi Q} - \frac{\delta}{4}, \quad \alpha = \frac{4\pi M_r}{H_c(1-S^*)}. \quad (51.27)$$

A comparison between the transition parameters for longitudinal (a_L) and perpendicular (a_P) recording from (51.5) and (51.27) with the parameters listed in Table 51.8 is shown in Fig. 51.34 [(H_c) for longitudinal recording is the dark line and (H_c) for perpendicular recording is dashed]. It is seen that the transition parameter for perpendicular recording can be made smaller than that for longitudinal recording if the coercive field for perpendicular recording is larger than 6500 Oe. Note that the thickness of the recording media for perpendicular recording is larger than that for longitudinal recording. The magnetic squareness (M_r/M_s) for perpendicular recording media is larger than that for longitudinal recording.

Gao and Bertram have shown a significant advantage for perpendicular recording if the uniaxial anisotropy is not aligned perpendicular to the surface, but oriented at

Fig. 51.34 Comparison of transition parameters versus the coercive field (H_c) for perpendicular (solid line) and longitudinal (dashed line) recording. (After [51.68])

45° to the perpendicular [51.70]. The geometry for this *tilted* perpendicular recording is shown as Fig. 51.35. The crystallites comprising the media are still aligned perpendicular but the crystalline anisotropy is assumed to be at 45°. No material system was disclosed that exhibits this tilted anisotropy. With tilted perpendicular recording the crystalline anisotropy field (H_k) can be made significantly larger than if the anisotropy is perpendicular. An example is 15 000 Oe for perpendicular recording and 28 000 Oe for tilted perpendicular recording [51.70]. Some of the advantages of tilted perpendicular recording are: reduced switching field and reduced average grain diameter, resulting in increased signal-to-noise ratio since the number of grains per bit is increased.

The requirements for media for ultra-high-density perpendicular recording have been analyzed [51.71]. Table 51.9 summarizes the results for media parameters for areal densities of 100–1000 Gb/in². Several key media parameters are the grains per bit (N) and the coercivity (H_c). An estimate of the signal-to-noise (SNR) ratio using the Poisson statistics of additive noise for the magnetic grains is

$$\text{SNR} = -10 \log_{10} (N) ,$$

where N is the number of magnetic grains per bit [51.71]. There are two approaches to realizing recording media with a large perpendicular anisotropy and that can approach the parameters in Table 51.9: granular media typified by CoCr alloys and *continuous* multilayer media typified by [Co–Pd]_n multilayers. CoCr alloys exhibit good SNR but insufficient H_c for ultra-high recording

Fig. 51.35 Typical geometry of tilted perpendicular recording. The medium anisotropy directions and not the medium grains are tilted in the cross-track direction. (After [51.70])

densities, while the multilayers have not exhibited sufficient SNR. Recent results for multilayers of Co/PdSi where the Pd layer is doped with silicon have shown an improvement in the SNR [51.59]. The technology demonstration of 50 + Gb/in² (to be discussed) used a granular CoCr alloy. Table 51.7 is a listing of some metal alloy candidates for perpendicular recording. In general, Pt plays a significant role in determining the magnetic anisotropy and Cr, Ta, Nb and B reduce the exchange coupling, resulting in reduced noise. Another alternative for perpendicular recording media is oxide media, e.g., CoCrPtO or CoCrPt–SiO₂ [51.63, 72, 73]. A recent study has shown that the oxide media has improved coercivity and a negative nucleation field (H_n), reduced pulse width and reduced signal decay compared to CoCrPtB media [51.74]. An issue with the oxide media is the nonuniformity of the coercivity and oxygen content in the disk surface due to the high gas pressure and oxygen-gas reactive sputtering [51.74]. The last two listings are for a *coupled granular/continuous* (CGC) medium that combines the best properties of the continuous media (high H_c and good thermal stability) and gran-

Table 51.9 Requirements for perpendicular recording media for ultrahigh recording densities (after [51.71])

Areal density (Gb/in ²)	100	250	500	1000
Flying height <i>d</i> (nm)	8	7	6	5
Signal-to-noise ratio (RMS signal/RMS noise)	18	17	16	15
Grains per bit <i>N</i>	63	50	40	32
Average grain diameter <i>D</i> (nm)	9	7	5	4

Coercivity <i>H</i> _c (Oe)	8500	11000	12500	14300

Fig. 51.36 Schematic representation for coupled granular/continuous (CGC) media. (After [51.64])

ular media (good SNR) [51.64, 65, 75]. A cross section of the CGC media is shown in Fig. 51.36 [51.64]. The continuous layer causes an exchange coupling which stabilizes the granular medium; this exchange field is large (≈ 200 kOe) and can result in considerable improvement in thermal stability [51.75]. The initial results for CGC media were encouraging from the standpoint of thermal stability but the high-density SNR was 2 dB less than for the granular media alone. Further optimization of the CGC media using [Co–Pt]_{*n*} multilayers coupled through a Pt buffer layer to a CoCrPt granular layer has shown an improvement in SNR over the granular media alone by 3–5 dB [51.75]. The improvement in SNR is believed to be due to the fact that magnetic recording transitions in the continuous layer are in the form of narrow domain walls and the magnetic interaction between the two layers may result in breaking up the magnetic clusters that form the transitions in the granular medium [51.75].

Magnetic materials used for the soft underlayer (SUL) for a perpendicular recording media must be magnetically soft for low reluctance but also must not exhibit magnetic domains, which can contribute noise to the read signal. The SUL must have a magnetic moment that is larger than that for the pole tip of the write element so that the SUL saturates *after* the pole tip saturates. This condition assures that there is no excess reluctance directly under the pole tip. The SUL must also be thick enough that the reluctance of the path through which the flux travels allows the maximum magnetic field under the gap. Decreasing the reluctance of the flux path also increases the gradient of the magnetic field from the pole, which reduces the length of the transition parameter (51.20) [51.48]. A guide for selecting the SUL thickness (*T*_{SUL}) is

$$T_{\text{SUL}} \approx \frac{A_{\text{pole tip}}}{C_{\text{pole tip}}} \frac{M_{\text{pole tip}}}{M_{\text{SUL}}} \quad (51.28)$$

where *A*_{pole tip} and *C*_{pole tip} are the area and the circumference of the pole tip, respectively, and *M*_{pole tip} and *M*_{SUL} are the saturation magnetizations of the pole tip of the write head and soft underlayer, respectively [51.48]. The effects of changing the thickness of the SUL on the recording parameters of a probe head are shown in Table 51.10 [51.48], where it is seen that the thickness and hence reluctance are key to head performance. Candidate materials for the SUL are listed

Table 51.10 Effect of the thickness of the FeAlN soft underlayer (SUL) on recording head parameters (after [51.48])

Thickness of FeAlN SUL ($4\pi M_s = 20$ kG)	0.1 μm	0.3 μm
Maximum magnetic field (kOe) at recording layer at saturation current (mA) (in parentheses)	16.3 (90)	17.7 (70)
Maximum head field gradient (Oe/nm)	175	550

Table 51.11 Magnetic materials for soft underlayers (SUL)

Material	B_s (kG) ($T \times 10^{-1}$)	Relative Permeability	Comments	Reference
Ni ₈₀ Fe ₂₀ (Permalloy)	10	1500–2000	Insufficient magnetic moment for SUL. Field gradient decreases at maximum field	[51.48]
Sendust (FeSiAl)	10	8000	Insufficient magnetic moment for SUL	[51.4]
FeAlN	20	2000	Sensitive to process conditions; believed to be less useful than FeCoB	[51.48]
FeCoB	20–24	200–240	Annealed to reduce stress	[51.76,77]
CoZrNb	14		Lower magnetostriction than FeCoB	[51.77]
NiFe ₁₇ Mo ₄				[51.78]
[Ni–Fe/Si] _n			Multilayers	[51.79]
IrMn/CoZrNb	14		IrMn antiferromagnetic film to reduce spike noise due to domain walls	[51.80]

in Table 51.11. A major issue with the soft underlayer is the motion of domain walls driven by the magnetic field from the write head which can lead to *spike* noise.

The last entry in Table 51.11 is for an antiferromagnetic pinning layer to prevent the motion of such domain walls.

Fig. 51.37 Cross-sectional view of a perpendicular head with a GMR sensor including the bottom and upper shields. The upper shield also serves as the auxiliary pole. (After [51.81])

Perpendicular Recording Demonstrations

Perpendicular recording has now been used in commercial disk drives. The first was the Toshiba 40 GB, 1.8 inch disk drive with an areal density of approximately 75 Gb/in², while more recently the capacity has been increased to 80 GB and the areal density to 133 Gb/in² (Toshiba 2006). Seagate has shipped 2.5 inch notebook drives with a capacity of up to 160 GB and an areal density of 132 Gb/in² (Seagate 2006). An earlier technology demonstration with an areal density of 52.5 Gb/in² was reported in 2001 [51.81] and one for approximately 100 Gb/in² in 2003 [51.82]. Recently, Hitachi Global Storage Technologies has reported an areal density of 230 Gb/in² using perpendicular magnetic recording and a tunneling current-perpendicular-to-the-plane (CPP) GMR read head (to be discussed) [51.83]. We show in Table 51.12 the parameters used for the two areal density demonstrations. In both cases a pole write head and a spin valve read head were used. The parameters for the ≈ 100 Gb/in² demonstration are close to those required for the ultra-high densities (> 100 Gb/in²) as described in Table 51.9, except that the coercivity is about one half that specified. A cross section of the write and read elements for the perpendicular recording head used in the 52.5-Gb/in² demonstration is shown in Fig. 51.37 [51.81]. The pole of the write head is identified as the “main pole” and the thick return pole and upper shield of the GMR sensor are identified as the “auxiliary pole/upper shield”. The read signal versus density (roll-off curve) for the 52.5-Gb/in² demon-

Fig. 51.38 Normalized voltage amplitude for a sequence of read signals from a perpendicular recording system versus linear density in kb/in. (After [51.81])

stration is shown in Fig. 51.38 and results from the increasing interference of positive and negative step pulses in a long string of transitions. At low densities a step response is observed in perpendicular recording since the GMR sensor detects the vertical component of the stray magnetization that reverses at the transition and at higher densities the response appears as a sinusoid. The decay in the signal at the low-density response is due to the insufficient bandwidth of the preamplifier. The read signal for isolated transitions can be described by the response function

$$h(t) = A \tanh \left(\frac{\ln 3}{T_{50}} t \right), \quad (51.29)$$

where A is one half of the signal amplitude and T_{50} is the time for the signal to rise from $-A/2$ to $A/2$. The step signals can be detected either by differentiating the signal to produce pulses, as with longitudinal recording, or with equalizer circuits that directly handle the step response. The channel performance as realized with simulator channels is listed in Table 51.12 and approximates the requirements of a practical system.

Seagate technology reported an areal density of 100 Gb/in² in November 2002 [51.84]. The linear density was 700 kb/in and the track density was 143 ktracks/in. Seagate has also reported an areal density of 170 Gb/in². The linear density was 1050 kb/in and the track density was 161 ktracks/in with a data rate of 483 Mb/s. However, in neither case was this areal density reported in a disk-drive product but rather was measured using a single disk and single head [51.85].

51.2 Magnetic Random-Access Memory

The application of the giant-magnetoresistive effect to recording heads that we have discussed assumed that the sense current is in the plane of the recording film. This is not the only possibility and devices with the current perpendicular to the plane (CPP) have been proposed both for magnetic recording read heads but also for fast magnetic random-access memory (MRAM). The CPP technology that shows the most promise for both the magnetic recording and memory application is the magnetic tunnel junction (MTJ). The MTJ involves a pinned and a free ferromagnetic film spaced by a thin *insulating* film, usually Al_2O_3 . Figure 51.39 shows the schematic of an MTJ used for the MRAM application, including orthogonal bit and word or digit lines and the stack of films comprising a basic MTJ [51.86, 87]. Figure 51.40 shows a more detailed stack of films for an MTJ, including synthetic antiferromagnetic films, antiferromagnetic pinning films and the free film. A typical MTJ has the following thickness values for the key films: antiferromagnet: 300 Å, $\text{Co}_{90}\text{Fe}_{10}$ ferromagnet: 20 Å, ruthenium: 8 Å, Al_2O_3 : 10–15 Å, $\text{Co}_{90}\text{Fe}_{10}$ ferromagnet: 20 Å. As for the spin valve, the use of $\text{Co}_{90}\text{Fe}_{10}$ films for the free layer enhances $\Delta R/R$ [51.20]. Figure 51.40 also shows $\Delta R/R$ for a typical MTJ (for a bit area of $0.6 \times 1.2 \mu\text{m}$) versus magnetic field with the multiple curves being taken over a 6-inch wafer: the maximum change is greater than 48% [51.87]. The change in resistance with orientation of the free layer relative to the pinned layer is significantly larger than for GMR technology, but a thin insulating layer between the ferromagnetic films is required. The memory architecture that has evolved has a single MOS transistor coupled to the MTJ and the word line. The current in the word line supplies the magnetic field along the easy axis of the free film and is insulated from the MTJ (Fig. 51.39). Switching of a soft-magnetic film with a magnetic field applied along the direction of an induced uniaxial anisotropy (the easy axis) and simultaneously along a direction orthogonal to the easy axis (the hard axis) has been discussed (e.g., [51.4]). The switching is described by a switching asteroid given by the following equation and shown in Fig. 51.41 (in the figure the easy and hard magnetic fields are normalized with respect to the anisotropy field H_k).

$$(H_{\text{easy}})^{2/3} + (H_{\text{hard}})^{2/3} = (H_k)^{2/3}$$

$$H_k = 2 \frac{K_u}{M}$$

Switching of the state of the magnetization will occur whenever the combination of easy- and hard-axis fields

is on the outside of the asteroid. The switching field can be significantly reduced if magnetic fields are applied along both the easy- and hard-axis directions and an optimum is to have the fields equal. The bit line is used to supply the hard-axis magnetic field and the word line the easy-axis field. For writing a bit the sense transistor is turned off and current pulses are applied along both orthogonal conductors, generating a magnetic field at the free film sufficient in amplitude to switch the magnetization of the free film. For reading a bit, the sense transistor is turned on by the word line and pulses of current are driven along the bit line (with the amplitude of the magnetic field insufficient to switch the free film) and the current is either high when the ΔR is low, corresponding to say a 1 or the current amplitude is low when ΔR is high, corresponding to a 0. Without the sense transistor there would be many *sneak paths* for the current through other MTJs, reducing the available current for reading the selected bit. The MTJ memory technology shows considerable promise for replacing semiconductor SRAM and DRAM memories, primarily because of the nonvolatility of the memory in the MRAM technology. The speed for reading data is comparable to that of SRAM and the density is comparable to that for DRAM.

The physics of the MTJ is different from that for GMR [51.88]. Ferromagnetic films have two types of

Fig. 51.39 Schematic of MRAM cross-point architecture with bits between orthogonal conductors and each cell defined by one MTJ and one transistor. The top lines in contact with the top electrode of the bits provides hard-axis fields, while the bottom lines are isolated and provide easy-axis fields. Turning on the transistor provides a current path so that the corresponding bit can be sensed. (After [51.86])

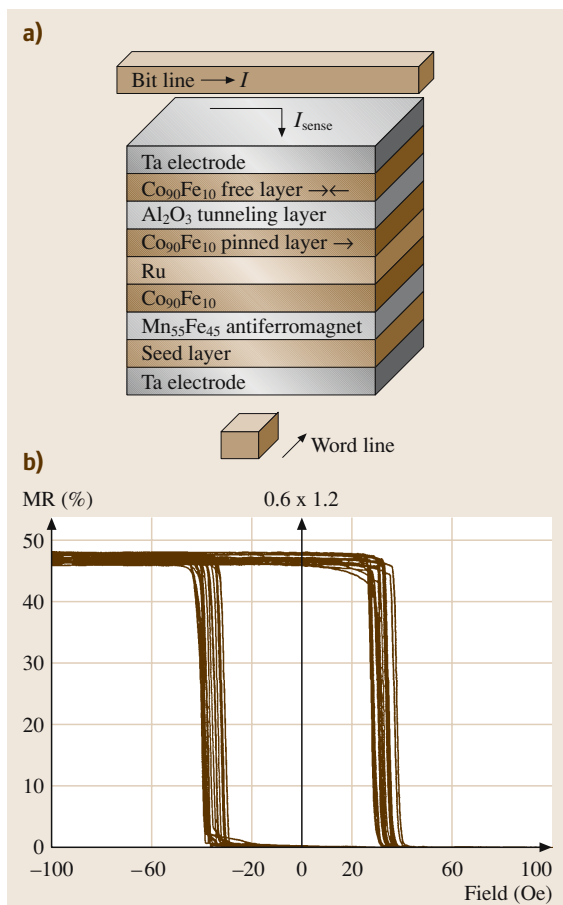

Fig. 51.40 (a) Stack of films comprising a typical MTJ. The arrows show the direction of the magnetizations in the two coupled films. (b) Hysteresis curves of $\Delta R/R$ versus magnetic field for $0.6 \times 1.2 \mu\text{m}$ bits on a 6-in wafer. (After [51.87])

electrons: those polarized parallel to the magnetization (\uparrow) and those polarized antiparallel to the magnetization (\downarrow). A polarization ratio (P) for a ferromagnetic material can be defined as

$$P = \frac{D(E_F)^\uparrow - D(E_F)^\downarrow}{D(E_F)^\uparrow + D(E_F)^\downarrow},$$

where $D(E_F)^\uparrow$ and $D(E_F)^\downarrow$ are the densities of states for electrons at the Fermi energy for the spin-up and spin-down electrons, respectively. The magnetoresistance ratio of two films coupled by an insulator is [51.89]

$$\frac{\Delta R}{R} = \frac{R_a - R_p}{R_p} = \frac{2P_1 P_2}{1 - P_1 P_2}, \quad (51.30)$$

Fig. 51.41 Switching asteroide plotted with magnetic fields normalized to the induced anisotropy field ($2K_u/M$). The ferromagnetic film will switch for any combination of easy- and hard-axis fields on the outside of the asteroide

where R_a and R_p are the resistances of the coupled films in the antiparallel and parallel configurations, respectively, and the spin polarizations are P_1 and P_2 for the two ferromagnetic films. Values of the spin polarization ratio are: $P_{\text{Co}} \approx 0.35$, $P_{\text{Fe}} \approx 0.44$ and $P_{\text{Permalloy}} \approx 0.3$ [51.88]. With cobalt used as one electrode and Permalloy for the other electrode, the predicted value for $\Delta R/R$ is 24%. Conduction through the insulating film is by quantum-mechanical tunneling, described by a transmission coefficient (T)

$$T = \frac{|\psi_{\text{transmitted}}(x)|^2}{|\psi_{\text{incident}}(x)|^2},$$

where $\psi(x)$ is the wavefunction for the electron plane wave and $|\psi(x)|^2$ is the probability of finding an electron at the position x . The transmission coefficient is a measure of the resistance of the barrier. The transmission coefficient for electrons with energy E tunneling through an insulating film of thickness a with amplitude of the barrier height of V_0 is given by

$$T = T_0 e^{-2\alpha a},$$

where

$$T_0 = \frac{16E(V_0 - E)}{V_0^2},$$

Table 51.13 Parameters for Permalloy (Ni₈₀Fe₂₀)

M_s (T)	K_1 (J/m ³)	A (exchange constant) (10 ⁻¹² J/m)	Critical length l_s (nm)
1.0	500	13	5.7

and

$$\alpha^2 = \frac{2m(V_0 - E)}{\hbar^2}.$$

This result applies when $\alpha a > 1$. A barrier height of 10 eV applies for CoO. The exponential dependence of the transmission coefficient on the thickness of the barrier shows the requirement for a thin barrier. A typical value of the thickness of an Al₂O₃ layer is 10 Å and the resistance changes by a factor of 100 million in changing the thickness from 0 to 10 Å. The reason that the MTJ is more attractive than a spin valve for the memory application is that the MTJ can be made with a resistance of many ohms, while the spin valve is nearly a short circuit. The use of the synthetic antiferromagnet for the MTJ also helps to avoid the superparamagnetic limit for this device, since the films comprising the synthetic antiferromagnet are thicker than the single antiferromagnetic film that was used to pin one of the ferromagnetic electrodes.

A significant problem with the MTJ is the different magnetic states that can be found depending on the size and shape of the bit. A review of an analysis of the states for a rectangular-shaped bit has been published [51.90] and we will quote some of their results to illustrate the problem. The analysis uses finite element analysis to solve the equation of motion for the magnetization (\mathbf{M}) with Gilbert damping in the presence of an effective magnetic field (\mathbf{H}_{eff})

$$\frac{d\mathbf{M}}{dt} = \gamma (\mathbf{M} \times \mathbf{H}_{\text{eff}}) - \frac{\alpha}{M} (\mathbf{M} \times \dot{\mathbf{M}}). \quad (51.31)$$

The effective magnetic field can be derived from the magnetic free-enthalpy density

$$\mathbf{H}_{\text{eff}} = -\delta g / \delta \mathbf{M}$$

and the magnetic free enthalpy per unit volume is given by the sum of terms

$$g = g_{\text{exchange}} + g_{\text{anisotropy}} + g_{\text{demagnetizing-field}} + g_{\text{external-field}}.$$

An example of this analysis is a rectangular film of thickness 20 nm, length 1 μm, width 1 μm with magnetic properties shown in Table 51.13. The exchange constant is $A = s^2 a^2 J_{\text{ex}} N_v / 2$, where s is the spin of the atom, a the lattice constant and N_v is the number of nearest-neighbor atoms per unit volume. The critical length determines the maximum size of the mesh used in the finite element analysis. Figure 51.42 shows three of the six states of the magnetization in the sample. The first two are high-remanence states referred to as S-type and C-type and can be formed if the starting conditions are a single-domain state. The last state shown is a low-remanence state with an off-center vortex. The last state is formed when the initial conditions are two domains along the long axis of the film. The total energies for the three states are shown in Table 51.14 and it is seen that the lowest energy is the low-remanence state. An issue with the MRAM is the possibility of exciting the different states in the storage cell that can then result in a different switching asteroid. Thin films with low-aspect-ratio bit shapes have been predicted to result in reduced propensity to excite the vortex structures [51.91]. Changing the shape of the bit may also assist in minimizing the vortex structures. Software for analyzing these problems is the LLG Micromagnetics SimulatorTM developed by M. R. Scheinfein (llg@dancris.com).

A recent development in MRAM architecture is to pass the write current through the MTJ to heat the element and to lower the threshold for writing [51.92].

Fig. 51.42a–c Configurations for spins in a Permalloy sample described in Tables 51.13 and 51.14. Figure (a) is an S-state, (b) is a C-state and (c) is an off-center vortex state. (After [51.90])

Table 51.14 Total energies for different spin configurations in the Permalloy film (described in the text and Table 51.13) (after [51.90])

Structure	G (10 ⁻¹⁸ J)
S-state	169 897
C-state	169 890
Shifted vortex state	79 616

This is accomplished by turning on the selection transistor (Fig. 51.39) during the write operation. The advantages of this modification to the MRAM architecture are:

1. since the selection at write is controlled by the temperature, selection errors are reduced,
2. the write threshold is reduced,
3. thermal instability limits are increased by using materials with larger switching fields at the operating temperature [51.92].

51.2.1 Tunneling Magnetoresistive Heads

Tunneling magnetoresistance (TMR) can be used in a magnetic recording read-head application. These TMR heads use the CPP orientation of the sense current and, as with the MRAM, the tunneling is done through a thin insulating barrier. A schematic at the air-bearing surface in the simplest form of such a TMR head is shown as Fig. 51.43 [51.93]. The insulating barrier (again usually fabricated from Al₂O₃ films) is shown on edge and the current flow is in the plane of the paper. Longitudinal bias to put the ferromagnetic TMR electrode films in a single-domain state and the top and bottom shields are shown. The GMR ratio with the TMR effect is large but the resistance × area (RA) product, which is the resistivity times the film thickness, may also be large, resulting in excessive shot noise. Shot noise is intrinsic to tunneling with the direct-current (DC) bias current required for GMR head operation and is the dominant noise source in the TMR head. Figure 51.44 is a plot of the TMR ratio in % versus the RA product for three different TMR structures all made from the basic structure: buffer/PtMn/CoFe/Ru/CoFe/AlO_x/CoFe/NiFe/cap [51.93]. The PtMn is an antiferromagnet, AlO_x is the insulating barrier (prepared by in situ oxidation) and CoFe/NiFe is the second electrode. The data points for TMR versus RA for this structure are labeled “Conv-btm” (conventional bottom) and the data points for the “Smooth-top” structure is for the PtMn layer on top

Fig. 51.43 Schematic drawing of the air-bearing surface view of a tunneling magnetoresistive (TMR) head. (After [51.93])

instead of the bottom, while the “Smooth-btm” data points are for a head made with smoother interfaces. The TMR % remains constant at ≈ 20% until a knee, below which the TMR % drops due to pinholes and incomplete insulation coverage. The stack of films is ion-milled and the stripe height is defined by lapping. Magnetic recording results showed the expected large signal ($V_{\text{peak-to-peak}} = 42 \text{ mV}/\mu\text{m}$) with a biasing current of 1 mA but the SNR was only 23.4 dB and was not deemed sufficient to demonstrate the required low error rate [51.93]. A significant problem with the TMR head is that there is a large resistance in parallel with the

Fig. 51.44 Correlation between TMR ratio and resistance area product (RA) in three structures: top- and bottom-type MTJ with smoother interfaces and bottom-type MTJ with conventional stacking that has relatively rough interfaces. (After [51.93])

large capacitance resulting from the tunneling barrier. This combination results in a low-pass filter and care is required to limit the capacitance. In the example discussed here the cut off linear density is near 580 kfc/in.

Because of the significantly larger value of ΔR for the CPP as opposed to the CIP technology, it is possible that CPP may become the dominant technology for read heads in the future.

51.3 Extraordinary Magnetoresistance (EMR)

An interesting development in read head technology is the discovery that narrow band gap and hence high-mobility semiconductors can be made to function as detectors of magnetic field [51.94]. The concept is based on the Lorentz force exerted on charge carriers by a magnetic field

$$F = q\vec{v} \times \vec{B},$$

here q is the charge, \vec{v} is the velocity of the charge carrier and \vec{B} is the magnetic flux density acting on the charge. Electrons have the highest mobility as compared to holes and are the carriers used. The electrons are driven by an external source similar to the sense current in GMR sensors in a high mobility semiconductor and are deflected by the external magnetic field

into a trajectory and the voltage drop in the semiconductor at low locations is used to sense the magnetic field. The III-IV semiconductor InSb was chosen for the initial work on EMS because of the high mobility of electrons of $60\,000\text{ cm}^2/\text{V s}$. However, a major limitation was the ability to maintain the high mobility in thin films ($< 100\text{ nm}$) required for read head applications and this was addressed by forming a thin-film quantum well heterostructure [51.94]. An advantage of such sensors is the lack of any magnetic noise since there are no magnetic materials involved in the head structure. No experimental results of such structures in read head applications has been reported. A review of EMR as magnetic field nanosensors has been reported by S. Solin [51.95].

51.4 Summary

It was the purpose of this chapter to review the current status of the technology of magnetic recording as used in disk drives. The emphasis was on the magnetic materials used in the application and on some of the technical problems that may limit the increase in areal density of the devices. The new technology of MRAM, which has evolved from the magnetic recording application, was also reviewed. It was found that a wide range of magnetic materials is essential for the advance of magnetic recording and the MRAM technology, including high-magnetization soft-magnetic materials for write heads, new antiferromagnetic alloys with high

blocking temperatures and low susceptibility to corrosion for pinning films in giant-magnetoresistive sensors and new ferromagnetic alloys with large values of giant magnetoresistance. A significant limitation to magnetic recording was found to be the superparamagnetic effect and new advances in multilayer ferromagnetic films to reduce the impact of the effect, but also to allow high-density recording, were discussed. Perpendicular recording as an alternative to longitudinal recording was reviewed and it was concluded that this technology will be the dominant recording technology in the future.

52. High-Temperature Superconductors

The discovery by J. G. Bednorz and K. A. Müller in 1986 that the superconducting state can exist in oxides at temperatures above 30 K stimulated research in the field of superconductivity and opened a new field of research. Within a few years a large number of cuprate superconductors with transition temperatures well above the boiling point of liquid nitrogen have been found. In this chapter an overview of the major families of high-temperature superconductors and their physical properties is presented.

Starting from the well-known characteristics of conventional superconductors, described in Sect. 52.1, the new phenomena observed in high-temperature superconductors are considered. The complexity of the physical properties of the cuprate superconductors is closely related to the fact that these materials are close to a metal–insulator transition. In Sects. 52.2 and 52.3 the crystal structures, the general trends for the critical temperatures, the anisotropy of the physical properties and the factors limiting the transport critical current density are discussed. Because of their importance in the field of electronics some features of thin films are presented in Sect. 52.4.

The binary compound MgB_2 is strictly speaking not a high-temperature superconductor. Nevertheless, an overview of the physical properties of this interesting metallic superconductor, charac-

terised by a transition temperature as high as 39 K, has been included in the present chapter (Sect. 52.5).

After the successful development of helium liquefaction techniques in the laboratory of Heike Kammerlingh Onnes at the University of Leiden, temperatures down to about 1 K became accessible for further research [52.1]. One of the first aspects to be studied was the electrical resistivity of pure metals at very low temperatures. The nearly temperature-independent residual resistivity of platinum and gold was found to decrease with increasing purity of the metals. In 1911 Kammerlingh Onnes found that, in contrast to the behaviour of platinum and gold, the electrical resistivity of mercury drops to an unmeasurably small value at

a temperature of 4.2 K, as shown in Fig. 52.1. The remarkable phenomenon of superconductivity had been discovered [52.1].

In addition to zero resistance, the superconducting state is characterised by perfect diamagnetism. *W. Meissner* and *R. Ochsenfeld* found in 1933 that, as soon as the superconducting state is reached, a magnetic field is expelled from the interior of a superconductor cooled in the presence of a static magnetic field [52.2]. In contrast to the shielding of a magnetic field applied to a material in the superconducting state, field expulsion cannot be explained by perfect conductivity. This Meissner effect

2001	J. Akimitsu et al. discover superconductivity at 39 K in MgB ₂ [52.15]

Fig. 52.1 Resistance–temperature plot for mercury obtained by Heike Kammerlingh Onnes

is therefore indeed an additional characteristic property of superconductors.

The discoveries listed in Table 52.1 provide an overview of the history of superconductivity. The development of the highest known critical temperatures in metals and oxides is shown in Fig. 52.2. Between 1911 and 1974, the critical temperatures T_c of metallic superconductors steadily increased from 4.2 K in mercury up to 23.2 K in sputtered Nb₃Ge films [52.16, 17]. Nb₃Ge held the record for the critical temperature in metallic

Fig. 52.2 The highest known critical temperatures of metallic and oxide superconductors

superconductors until the unexpected discovery of superconductivity at 39 K in the intermetallic compound MgB₂ [52.15].

The first superconducting oxide SrTiO₃ characterised by a transition temperature as low as 0.25 K was discovered in 1964 [52.18]. A remarkably higher critical temperature of 13 K was found for the perovskite BaPb_{1-x}Bi_xO₃ in 1975 [52.19]. These results

Fig. 52.3 The efficiency of real refrigerators normalised to the Carnot efficiency is typically in the hatched area. The ratio of η_r/η_C increases with increasing refrigeration capacity. (After [52.21])

stimulated *J. G. Bednorz* and *K. A. Müller* to search for higher critical temperatures in oxides. Their discovery of high-temperature superconductivity in the cuprate $(\text{La, Ba})_2\text{CuO}_4$ ($T_c \approx 30$ K) opened up a new field of research [52.12]. Within less than a year a critical temperature well above the boiling point of liquid nitrogen could be achieved in $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ [52.20]. So far, the highest transition temperature of 135 K at ambient pressure has been found in $\text{HgBa}_2\text{Ca}_2\text{Cu}_3\text{O}_{8+\delta}$ [52.13, 14].

Finally, it should be mentioned that the phenomenon of superconductivity has also been observed in organic materials [52.22–24] and fullerenes [52.25–27]. Remarkably high transition temperatures of 19, 33 and 40 K

have been found in the fullerenes K_3C_{60} , $\text{RbCs}_2\text{C}_{60}$ and Cs_3C_{60} respectively.

An important advantage of high-temperature superconductors is the possibility of operating devices at temperatures well above 20 K, leading to a considerable reduction in the required refrigerator input power. In contrast to power applications, the use of liquid nitrogen as a coolant is of less importance for superconducting electronics, which are typically cooled by closed cycle coolers. The economics of closed cycle coolers depends strongly on the operating temperature. Considering an ideal, reversible cooling cycle, the input power necessary to remove a heat load dQ/dt is

$$P_{\text{in}} = \frac{1}{\eta_C} \frac{dQ}{dt}, \quad (52.1)$$

where

$$\eta_C = \frac{T_{\text{op}}}{300 \text{ K} - T_{\text{op}}} \quad (52.2)$$

is the Carnot efficiency. To remove a heat input of 1 W an ideal, reversible refrigerator consumes at room temperature a power of 70 W for $T_{\text{op}} = 4.2$ K, whereas this power is only 9 and 2.9 W for operation at 30 and 77 K, respectively. The efficiency η_r of real refrigerators is much smaller than the Carnot efficiency and depends strongly on the refrigerator size, as illustrated in Fig. 52.3. For small refrigerators able to remove a power of 1 W, the refrigerator efficiency is only a few percent of the Carnot efficiency. On the other hand, large refrigerators with a cooling capacity well above 10 kW may reach 30% of the Carnot efficiency. The ratio η_r/η_C has been found to depend only weakly on the operating temperature.

52.1 The Superconducting State

52.1.1 Characteristic Properties of Superconductors

The discussion of the physical properties of high-temperature superconductors has to be based on the knowledge of the behaviour of conventional, metallic superconductors. In this section the superconducting state is therefore described in more detail starting, from the properties of simple, metallic superconductors.

Below a certain temperature T_c the electrical resistance of a superconducting material vanishes. The critical temperature T_c is characteristic of the superconductor in question. In pure metals the zero resistance

state can be reached within a few mK (Fig. 52.1). In the chemically complex cuprate, high- T_c superconductors the transition to the superconducting state is less sharp than in metallic low- T_c superconductors. The transition width ΔT_c for single-phase cuprate superconductors is typically 1 K. Thus the critical temperature depends slightly on the criterion used to define T_c . Several criteria are illustrated in Fig. 52.4.

At the transition temperature a resistance drop of several orders of magnitude is typically observed. However, it is in principle not possible to prove experimentally that the resistance in the superconducting state is in fact zero. The most efficient way to determine

Fig. 52.4 Resistance versus temperature for a $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_8/\text{Ag}$ multi-core wire. The transition temperatures resulting from different definitions of T_c are indicated. The width of the transition $\Delta T_c = T_c(90\%) - T_c(10\%)$ is ≈ 1.2 K

an upper limit of the resistance is to detect the decay of the magnetic fields generated by currents induced in a superconducting loop. Upper resistivity limits between 2×10^{-18} [52.28] and $7 \times 10^{-23} \Omega \text{ cm}$ [52.29] have been reported for the high- T_c superconductor $\text{YBa}_2\text{Cu}_3\text{O}_7$, while a value of $3.6 \times 10^{-23} \Omega \text{ cm}$ has been found for type I low- T_c superconductors [52.30]. These upper resistivity limits are orders of magnitude smaller than the resistivity of $10^{-10} \Omega \text{ cm}$ at 4.2 K achievable in annealed, very pure metals. It is therefore justified to assume zero resistance below T_c for all practical purposes.

The second outstanding feature of the superconducting state is perfect diamagnetism. To understand the magnetic behaviour of a superconductor, the two different situations illustrated in Fig. 52.5 have to be considered. In the first case the superconductor is cooled below T_c without an applied magnetic field (zero field-cooled). In the second case the superconductor is cooled below T_c while a magnetic field is applied (field-cooled). In both cases the magnetic flux is excluded from the interior of the superconductor. Screening currents flowing in the surface layer of the superconductor generate a flux opposite to that of the applied magnetic field. The magnetic flux density is therefore zero everywhere inside the superconductor. On the other hand, outside the superconducting sphere the magnetic field is enhanced because of the superposition of the flux of the

Fig. 52.5 The magnetic flux is excluded from the interior of a superconductor without field-cooling (*left*) as well as with it (*centre*). In contrast to this behaviour, a magnetic flux would exist in the interior of a field-cooled perfect conductor (*right*) ([52.31] p. 20)

applied magnetic field and that of the screening currents. In both situations the superconductor is unmagnetised when the magnetic field is removed. The behaviour of a zero field-cooled superconductor may be considered simply as a screening effect caused by perfect conductivity. In contrast to screening, the expulsion of the magnetic flux from a field-cooled superconductor (the Meissner effect) cannot be explained by perfect conductivity. The different behaviour of a field-cooled perfect conductor is also shown in Fig. 52.5. The values of the relative magnetic permeability for non-ferromagnetic metals is close to unity. Thus the magnetic flux inside the metal is nearly the same as that of the applied magnetic field. Because $dB/dt = 0$ no screening currents are induced, and hence the magnetic flux is not removed from the interior of the perfect conductor at low temperatures. Finally, the removing of the magnetic field ($dB/dt \neq 0$) leads to magnetisation of the perfect conductor.

The superconducting state can be destroyed by a sufficiently large applied magnetic field. The transition from the superconducting to the normal state occurs at a certain critical magnetic field B_c , which is a characteristic property of the superconductor considered. The dependence of the critical field on the temperature is

Fig. 52.6 Critical field versus temperature curves for selected metallic superconductors. The B_{c0} values vary from ≈ 10 to ≈ 80 mT ([52.31] p. 24)

typically well described by

$$B_c(T) = B_{c0} \left[1 - \left(\frac{T}{T_c} \right)^2 \right] \quad (52.3)$$

where T_c is the critical temperature and B_{c0} the critical field at zero temperature. The critical field as a function of temperature is shown in Fig. 52.6 for selected metallic superconductors. The $B_c(T)$ curves separate the superconducting from the normal state. The Meissner effect ensures that the properties at any point in the superconducting state are independent of the order in which the final conditions of applied magnetic field and temperature are reached.

52.1.2 Superconductor Electrodynamics

The electrodynamics of superconductors can be described by the two London equations. As a consequence of the infinite conductivity in the superconducting state, Ohm's law must be replaced by the first London equation

$$\frac{d\mathbf{j}}{dt} = \frac{1}{\mu_0 \lambda_L^2} \mathbf{E}, \quad (52.4)$$

where \mathbf{j} is the current density, \mathbf{E} the electric field, μ_0 is the permeability of free space and λ_L a constant. The electric field in the superconductor is zero for constant current density. The current density and the magnetic field are related by the second London equation.

$$\text{curl} \mathbf{j} = -\frac{1}{\mu_0 \lambda_L^2} \mathbf{B}. \quad (52.5)$$

Fig. 52.7 Exponential decay of an applied magnetic field in the surface layer of a semi-infinite superconductor. The normalised penetration depth λ_L/λ_{L0} versus reduced temperature is shown in the inset

Using the Maxwell equation $\text{curl} \mathbf{B} = \mu_0 \mathbf{j}$ the following differential equation results for the magnetic field

$$\nabla^2 \mathbf{B} = \frac{1}{\lambda_L^2} \mathbf{B}. \quad (52.6)$$

For a semi-infinite superconductor with the magnetic field applied along the z -direction, an exponential decay of the magnetic field $B(x) = B_0 \exp(-x/\lambda_L)$ results, as illustrated in Fig. 52.7. The London penetration depth λ_L is therefore the characteristic length for the decay of the magnetic field in the surface layer of the superconductor. Typical values of the penetration depth are 10^{-5} – 10^{-6} cm at $T = 0$. The penetration depth is closely related to the number density of the Cooper pairs (Sect. 52.1.3)

$$\lambda_L = \sqrt{\frac{m_C}{\mu_0 n_C q_C^2}}, \quad (52.7)$$

where n_C , q_C and m_C are the number density, the charge and the mass of the Cooper pairs. Because of the decreasing Cooper pair density, the penetration depth increases rapidly for temperatures close to T_c (see inset of Fig. 52.7). The temperature dependence is given by

$$\lambda_L(T) = \lambda_{L0} \left[1 - \left(\frac{T}{T_c} \right)^4 \right]^{-1/2}, \quad (52.8)$$

where λ_{L0} is the penetration depth at $T = 0$.

52.1.3 Superconductivity: A Macroscopic Quantum Phenomenon

Bardeen–Cooper–Schrieffer (BCS) Theory

Next, the microscopic causes of superconductivity in conventional superconductors are briefly described. *J. Bardeen, L. N. Cooper, and J. R. Schrieffer* proposed a microscopic theory of superconductivity [52.4, 5], which is now well known as the BCS theory. At the moment it seems to be unlikely that the mechanism of superconductivity in the cuprates, which is still not yet understood, can be explained by the BCS theory. In this chapter only some fundamental ideas and results of the BCS theory are presented.

Independently of each other, two researchers [52.32, 33] found theoretically that lattice vibrations (phonons) can provide an attractive interaction between two electrons. This can be understood as a consequence of the polarisation of the lattice by the electrons. The concentration of positive charges produced by the first electron reduces the potential energy of the second electron. Because of this attractive interaction, electrons with opposite momenta and spins form electron (Cooper) pairs. The Cooper pairs, characterised by zero spin and momentum, have to be considered as new particles. Because their spin is zero, they do not obey Pauli's exclusion principle. The probability that a state is occupied increases with the number of particles populating the same quantum state. Therefore, all Cooper pairs occupy the same quantum state with a single value of the momentum in the presence of an applied electric field. A change of momentum results only for scattering processes that break up some Cooper pairs. Resistance occurs as soon as the energy taken from the electric field exceeds the binding energy of the Cooper pairs. This behaviour explains the existence of a critical current.

The electron–phonon interaction leads to an energy gap 2Δ in the density of states for the single electrons. The width of the energy gap at zero temperature is

$$2\Delta(0) = 3.5k_B T_c, \quad (52.9)$$

where k_B is the Boltzmann constant and T_c the critical temperature. For superconducting elements the measured ratios of $2\Delta(0)/k_B T_c$ are typically 3.2–4.6 [52.34], which is in reasonably good agreement with the value of 3.5 predicted by the BCS theory. The single-electron density of states close to the Fermi energy is

$$D_s(E - E_F) = D_n(E_F) \frac{|E - E_F|}{\sqrt{(E - E_F)^2 - \Delta^2}}, \quad (52.10)$$

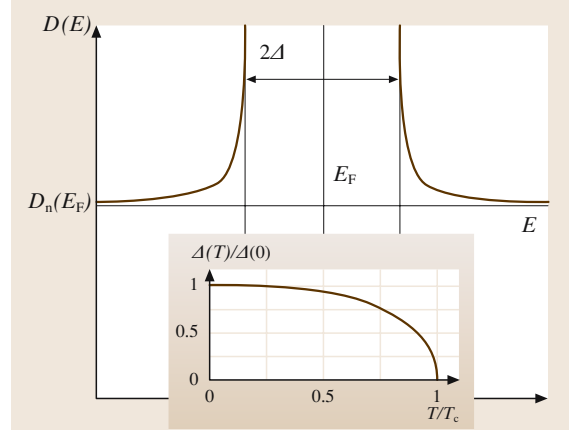

Fig. 52.8 Energy gap and density of states for unpaired electrons in the superconducting state in the vicinity of the Fermi energy E_F . The temperature dependence of the energy gap predicted by the BCS theory is shown in the inset

where Δ is the half-width of the energy gap and $|E - E_F| > \Delta$. The variation of the normal state density of states $D_n(E)$ can be neglected because $E_F \gg 2\Delta$. The single-electron density of states shown in Fig. 52.8 reflects that the energy states present in the normal state within the energy gap are shifted to the edges. The inset of Fig. 52.8 shows the temperature dependence of the energy gap predicted by the BCS theory. The critical temperature is [52.5]

$$T_c = 1.14 \frac{\hbar\omega_D}{k_B} \exp\left(-\frac{1}{D_n(E_F)V_p}\right), \quad (52.11)$$

where the electron–phonon interaction is described by the constant V_p . The Debye frequency ω_D is the cut-off frequency of the phonon spectrum in a solid. Considering the atoms in a solid as harmonic oscillators of frequency $\omega = (k_e/M)^{1/2}$, where k_e is the elastic constant resulting from the binding forces, both ω_D and T_c are expected to be proportional to $M^{-1/2}$ for different isotopes of the same element. In many metallic superconductors this isotope effect has been observed [52.35–38].

All Cooper pairs populate the same quantum state, resulting in a collective wave function

$$\psi = n_C^{1/2} \exp[i\varphi(\mathbf{r})], \quad (52.12)$$

where $n_C = \psi^*\psi$ (ψ^* : conjugate complex of ψ) is their concentration. Because the phase coherence of the Cooper pairs is effective at large distances, the phase

$\varphi(\mathbf{r})$ is a macroscopically observable quantity. As a consequence, the magnetic flux in a superconducting hollow cylinder of cross-sectional area F is quantised

$$\phi = \int_F \mathbf{B} \cdot d\mathbf{F} = \frac{h}{2e} N_\phi = \phi_0 N_\phi. \quad (52.13)$$

In the above equation N_ϕ is an integer, e the electron charge and $\phi_0 = 2.068 \times 10^{-15} \text{ V s}$ the flux quantum. The magnetic flux generated by the screening currents flowing in the surface layer of the superconductor is typically small, and has therefore been neglected.

Tunnelling Effects

First, single-electron tunnelling in a normal–insulator–superconductor (N-I-S) junction will be considered. The two conductors are separated by an insulating oxide layer typically less than 2 nm thick. Tunnelling can take place only when empty target energy states are available, otherwise the process is forbidden by the Pauli principle (Fig. 52.9). For a voltage of $U = \Delta/e$ ($-e > 0$) the empty energy states of the superconductor above the energy gap reach the same level as the Fermi energy of the normal conductor, and strong tunnelling sets in. On the other hand for a voltage $U = -\Delta/e$, pair breaking becomes possible. One of the electrons tunnels into the normal conductor and gains an energy Δ available for the exci-

tation of the second electron to an empty state above the energy gap. The resulting N-I-S current–voltage characteristic and the Bose condensation representation of the tunnelling process are shown in Fig. 52.9.

In the case of two identical superconductors (S-I-S junction), strong single-electron tunnelling sets in at an applied voltage $|U| \geq |2\Delta/e|$. This voltage is high enough to allow the empty energy states above the gap of the first superconductor, and the filled energy states below the gap of the second superconductor, to overlap; pair breaking becomes possible. Figure 52.10 shows the semiconductor representation of the tunnelling process and the resulting S-I-S current–voltage characteristic. The weak tunnelling currents for $|U| < |2\Delta/e|$ are a consequence of a few quasi-particles being thermally excited above the energy gap for $T > 0$ (Fig. 52.10).

So far, only single-electron tunnelling has been considered. In 1962 *B. D. Josephson* predicted that Cooper pair tunnelling through a very thin insulating layer is possible [52.10]. Even for zero voltage across the insulating layer of an S-I-S junction, Cooper pairs can tunnel through the barrier. This process has to be considered as

Fig. 52.9 Bose condensation representation of N-I-S tunnelling (top) and the corresponding current voltage characteristic at $T = 0$

Fig. 52.10 Current voltage characteristic of an S-I-S tunnel junction (bottom). Strong tunnelling sets in for $U = |2\Delta/e|$. The semiconductor representation of the process (top) shows that a few electrons (quasi particles) are thermally excited into states above the gap at $T > 0$. These electrons are responsible for the weak tunnelling current at low voltages ([52.31] p. 42)

the tunnelling of the wave function collectively describing the Cooper pairs. The DC current through the contact is

$$I = I_c \sin \delta, \quad (52.14)$$

where I_c is the critical current of the Josephson junction. The Josephson DC current through the contact is between $-I_c$ and I_c , depending on the phase difference δ of the two Cooper pair wave functions. This phase difference is time independent for zero voltage across the insulating layer. Applying a DC voltage U across the insulating layer of the Josephson contact causes a time-dependent phase difference between the two Cooper pair wave functions. As a consequence there flows an AC current

$$I_{AC} = I_c \sin [2\pi\nu_J t + \delta(0)], \quad (52.15)$$

where

$$\nu_J = \frac{2|e|U}{h} = \frac{U}{\phi_0}. \quad (52.16)$$

The AC Josephson current I_{AC} oscillates with a frequency of 483.6 MHz/ μ V. The tunnelling of the Cooper pair through the barrier is connected to the emission or absorption of a photon with energy $E = h\nu_J$. The AC Josephson current flows in addition to the current resulting from single-electron tunnelling. A more detailed description of the AC Josephson effect can be found in [52.34].

Finally, macroscopic quantum interference effects in Josephson junctions will be briefly considered. These interference effects are closely connected to the phase shifts of the Cooper pair wave functions caused by a magnetic field applied transversely to the current direction. The applied magnetic field gives rise to a spatial variation of the phase difference of the two Cooper wave functions within the contact area. The resulting Josephson DC current for a rectangular barrier is

$$I = I_c \sin \delta_0 \frac{\sin \pi\phi/\phi_0}{\pi\phi/\phi_0}, \quad (52.17)$$

where I_c is the critical current of the Josephson junction, ϕ the total flux enclosed by the barrier, and ϕ_0 the flux quantum. The phase shift δ_0 is unknown. The maximum Josephson DC current

$$I_{\max} = I_c \left| \frac{\sin \pi\phi/\phi_0}{\pi\phi/\phi_0} \right| \quad (52.18)$$

Fig. 52.11 Josephson–Fraunhofer diffraction pattern for the normalised maximum Josephson DC current I_{\max}/I_c . Minima of the current occur for Φ/Φ_0 values of 1, 2, 3 etc.. (After [52.31] p. 49)

is reached for $\sin \varphi_0 = 1$, corresponding to a phase difference of $\pi/2$. In Fig. 52.11, the resulting interference pattern for the Josephson DC current is shown. The Josephson–Fraunhofer interference of the two Cooper pair wave functions indicates that superconductivity is a macroscopic quantum phenomenon (for more details see [52.31]).

52.1.4 Type II Superconductors

A quantitative description of the behaviour of type II superconductors is provided by the Ginzburg–Landau theory (see for example [52.34]). In the London theory the Cooper pair density is assumed to be constant. The only characteristic length scale is the penetration depth λ_L describing the decay of a magnetic field inside a superconductor. Taking into consideration a variation of the Cooper pair density leads to a second characteristic length scale, namely the coherence length ξ , the shortest distance within which a considerable change of the Cooper pair density can occur. At the interface of a normal and a superconductor the Cooper pair density increases continuously from zero to the value n_C deep inside the superconductor. The ratio of the coherence length and the penetration depth is the Ginzburg–Landau parameter κ

$$\kappa = \frac{\lambda_L}{\xi}. \quad (52.19)$$

Fig. 52.12 Comparison of the phase diagrams for type I and II superconductors. (After [52.31] p. 74)

Depending on whether the parameter κ is smaller or larger than $1/\sqrt{2}$, the superconductor in question is of type I or II, respectively. Values of the coherence length and the Ginzburg–Landau parameter of selected metallic superconductors are listed in Table 52.2. The cuprate high- T_c superconductors are extreme type II superconductors with κ values of ≈ 100 .

In Fig. 52.12, the phase diagrams of both types of superconductors are compared. In type I superconductors there exist two different phases, namely the superconducting and the normal, which cannot coexist. On the other hand, three different phases can exist in type II superconductors. Below the lower critical field $B_{c1}(T)$ the type II superconductor is in the superconducting phase characterised by perfect diamagnetism, where it behaves like a type I superconductor. Above the upper critical field $B_{c2}(T)$ the material is in the normal state. In the mixed state between the lower and upper critical fields superconducting and normal regions can coexist in a type II superconductor. The mixed state shown in Fig. 52.13 is characterised by an array of normal cores within the superconductor, which allow magnetic flux to enter into the superconductor. The supercurrents encircling the normal cores (vortices) cause a repulsive vortex–vortex interaction.

In the mixed state of a type II superconductor the transport currents can flow throughout the conductor. In the presence of a magnetic field perpendicular to the current direction a Lorentz force $F_L = j\phi_0$ acts

Fig. 52.13 Type II superconductor in the mixed state. Each vortex contains just a single fluxoid $\Phi_0 = h/2|e|$. (After [52.31] p. 74)

on the vortices, which leads to a motion of the vortices perpendicular to the current and the field direction. The variation of the magnetic flux leads to a flux flow resistance, and hence the critical current would be zero. However, in a real type II superconductor defects are always present, which act as pinning centres. As long as the Lorentz force is smaller than the pinning force, flux motion is suppressed, resulting in zero resistance.

52.2 Cuprate High- T_c Superconductors: An Overview

52.2.1 Major Families of Cuprate Superconductors

At present around 100 cuprate superconductors are known. The major families of cuprate superconductors are listed in Table 52.3. Common features of the cuprate superconductors are layered crystal structures. In the cuprates, conducting copper oxide blocks and insulating charge-carrier reservoirs alternate with each other along the crystallographic c direction. As a consequence of the layered structures the physical properties of the cuprates are highly anisotropic. The electrical resistivity along the crystallographic a - and b -directions within the conductive CuO_2 planes is much lower than along the c -direction, where the current has to cross the insulating charge-carrier reservoirs. Figure 52.14 shows as an example the layering scheme of $\text{Tl-}22(n-1)n$ superconductors. The three thallium-based compounds are distinguished by the different number n of CuO_2 planes in the copper oxide blocks. In the compounds with $n \geq 2$, adjacent CuO_2 planes are separated by Ca layers. In the $\text{Bi-}22(n-1)n$ counterparts Tl and Ba are replaced by Bi and Sr, respectively. In both families of cuprate superconductors the copper oxide blocks are embedded between TlO or BiO double layers. An analogous layering scheme results for the $\text{Tl-}12(n-1)n$ compounds. However, the copper oxide blocks of these compounds are separated only by single TlO layers. The highest critical temperature is typically reached in the compounds with three CuO_2 layers ($n = 3$) in the copper oxide blocks.

Table 52.2 Coherence length ξ_c and Ginzburg–Landau parameter κ for selected superconductors at $T = 0$ ([52.31] p. 70)

Material	$T_c(\text{K})$	$\xi(\text{nm})$	$\kappa = \lambda_L/\xi$	Reference
Al	1.18	550	0.03	[52.34]

YBa ₂ Cu ₃ O _{7-δ}	93	2	95	[52.34]

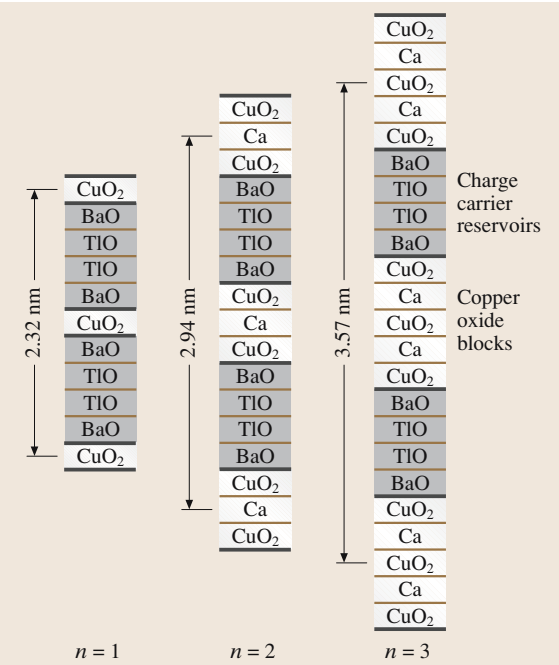

Fig. 52.14 Layering scheme of $\text{Tl}_2\text{Ba}_2\text{Ca}_{n-1}\text{Cu}_n\text{O}_{2n+4}$ superconductors (After [52.31] p. 81)

The physical properties of the cuprate superconductors depend strongly on their chemical composition and the resulting carrier concentration. As in semiconductors, the carrier concentration in the cuprates can be changed by doping. For example let us consider the superconductor $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$. The possible oxidation states of copper are +1, +2 and +3. In the insulating parent compound La_2CuO_4 the oxidation state of copper is +2. The valence of La is +3 and that of Sr +2. Substitution of Sr^{2+} for La^{3+} leads to the formation of Cu^{3+} or O^- defects (holes), which are expected to be mobile. Thus, an increasing number of holes is created in the CuO_2 planes with increasing Sr concentration x .

The cuprates are complex non-stoichiometric oxides. Heat treatments in reducing or oxidising atmosphere therefore lead to considerable changes in the oxygen content. Incorporation of excess oxygen is a further way to enhance the hole concentration in the CuO_2 planes of the cuprates.

Finally, it should be noted that, in addition to the major families of cuprate superconductors listed in Table 52.3, there exists a large number of high-

temperature superconductors which can be synthesised only under high pressure (see for example [52.31]).

52.2.2 Generic Phase Diagram of Cuprate Superconductors

It is beyond the scope of this article to discuss all the new physical phenomena related to cuprate superconductors. To give an impression of the complexity of

Fig. 52.15 Generic phase diagram for cuprate superconductors indicating that these materials are close to a metal–insulator transition. The physical properties of the cuprates vary considerably with increasing hole concentration

these materials the generic phase diagram is briefly described. The one shown in Fig. 52.15 indicates that the cuprate superconductors are close to a metal–insulator transition. Their parent compounds are antiferromagnetic insulators, of which La_2CuO_4 and $\text{YBa}_2\text{Cu}_3\text{O}_6$ are examples. The Néel temperature T_N , at which magnetic ordering sets in, reaches values of 250–400 K in the parent compounds. The Néel temperature decreases rapidly with increasing hole concentration. A transition from an insulating to a superconducting phase is observed for further enhanced doping levels. The critical temperature increases with increasing number of holes and reaches a maximum at ≈ 0.18 holes per CuO_2 unit before decreasing again. At doping levels well above 0.3 holes/ CuO_2 the material behaves as a non-superconducting metal.

In the last few years it could be clarified that the energy gap in cuprate superconductors is of d-wave symmetry, whereas it is of s-wave symmetry in conventional superconductors. The two different symmetries are illustrated in Fig. 52.16. For s-wave symmetry the superconducting energy gap is constant irrespective of the direction of the wave vector k . In the case of d-wave symmetry there exist positions on the Fermi surface for which the energy gap is zero. At these positions the sign of the order parameter changes from + to – or vice versa. As a consequence a finite tunnel conductivity [$dI/dV \propto D(E)$] is observed within the energy gap (see Fig. 52.16).

Next, let us consider the temperature dependence of the energy gap. The tunnelling conductance of underdoped Bi-2212 shown in Fig. 52.17 indicates that

Fig. 52.16 The two different symmetries of the energy gap and the corresponding density of states. For s-wave symmetry (left) the width of the energy gap is independent of the wave vector k . In the case of the d-wave symmetry (right) the energy gap depends on the wave vector. At four positions on the Fermi surface the energy gap is zero (After [52.42])

Fig. 52.17 Schematic illustration of the tunnelling conductance of underdoped Bi-2212 providing the density of states in the vicinity of the energy gap. For clarity the spectra are offset vertically. A gap-like feature (pseudogap) can be observed even at a temperature as high as 175 K, well above T_c (After [52.43])

the energy gap of cuprate superconductors is independent of temperature. This behaviour is in contrast to the predictions of the BCS theory. In underdoped cuprate superconductors the energy gap has been found to increase for decreasing number of charge carriers in spite of a reduced critical temperature. On the other hand, both the energy gap and the critical temperature of overdoped cuprates decrease with increasing carrier concentration. An outstanding feature of cuprate superconductors is the existence of an energy gap even at temperatures well above T_c . This pseudogap is found in the region of the phase diagram where a transition from an antiferromagnetic insulator to a superconductor occurs.

New theories have predicted that in underdoped cuprate superconductors, spin and charge are separated, resulting in antiferromagnetic domains and charge stripes located at the anti-phase boundaries [52.44]. Experimental evidence for this scenario has been found from neutron scattering [52.45]. A potential explanation for the existence of the pseudogap is the formation of Cooper pairs at temperatures well above T_c . However, because of the small Cooper pair density, they are not macroscopically correlated. As a consequence the material is not able to carry a supercurrent above T_c . At present it is not clear if the interplay of anti-

ferromagnetism and charge stripes is responsible for high-temperature superconductivity.

52.2.3 Crystal Structures

Next, let us consider the crystal structures of the cuprates in more detail. For $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ (Y-123) an orthorhombic structure with lattice parameters $a = 0.38 \text{ nm}$, $b = 0.39 \text{ nm}$ and $c = 1.17 \text{ nm}$ has been deduced from X-ray powder diffraction data [52.46, 47]. Figure 52.18 shows the orthorhombic unit cell of Y-123. The unit cell of $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ contains double CuO_2 layers with embedded yttrium ions (Fig. 52.18). Slightly different z positions of the Cu and O atoms lead to buckling in the CuO_2 planes. The oxygen atoms occupy perovskite-like anion positions halfway between the copper atoms. These square-coordinated CuO_2 layers are a characteristic feature of all cuprate superconductors. Because metallic conductivity has been found in these layers, they are also called conduction planes. Along the crystallographic c -axis perpendicular to these planes, insulating or semiconducting behaviour

Fig. 52.18 Orthorhombic unit cell of $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$. A special feature of this cuprate are CuO chains in the b -direction (After [52.31] p. 100)

Fig. 52.19 Primitive tetragonal unit cell of $\text{TlBa}_2\text{Ca}_2\text{Cu}_3\text{O}_9$ (After [52.31] p. 108)

is frequently observed. Neighbouring CuO_2 blocks are separated by two BaO layers. The CuO chains between the two BaO layers in the b -direction are a special feature of the Y-123 compound.

The crystal structures of $\text{Tl-}12(n-1)n$ and the analogous $\text{Hg-}12(n-1)n$ superconductors are primitive tetragonal. Because of the common CuO_2 planes, the a and b lattice parameters of cuprate superconductors are generally close to 0.39 nm. In both cuprate superconductor families the c lattice parameter is given approximately by $c \cong (0.63 + 0.32n)\text{nm}$. As an example of these crystal structures the primitive tetragonal unit cell of $\text{TlBa}_2\text{Ca}_2\text{Cu}_3\text{O}_9$ is shown in Fig. 52.19. The copper oxide blocks of the Tl-1223 compound are formed of three CuO_2 layers. The CuO_2 layers within the copper oxide blocks are separated by Ca ions. In contrast to the $\text{Tl-}22(n-1)n$ compounds (see Fig. 52.14) adjacent CuO_2 blocks are separated by only

Table 52.3 Major families of superconducting cuprates ([52.31] p. 79)

Family	Symbol	Maximum T_c (K)
$(\text{La}_{1-x}\text{M}_x)_2\text{CuO}_4^{\text{a}}$	La-214	39
$\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}^{\text{b}}$	Y-123	92
$\text{YBa}_2\text{Cu}_4\text{O}_8$	Y-124	80

a single TlO layer. Like the TlO double layers of the $22(n-1)n$ compounds, the single TlO layers of the $12(n-1)n$ compounds are embedded between two BaO layers. The reduced distance of neighbouring copper oxide blocks leads to an enhanced coupling of the conduction planes. This improved coupling is reflected in less-anisotropic superconducting properties (Sect. 52.3). Defects in the $\text{BaO}/\text{TlO}/\text{BaO}$ layers forming the charge-carrier reservoirs provide holes for the doping of the CuO_2 planes. In the $\text{Tl-}12(n-1)n$ compounds the BaO layers can be replaced by SrO layers. The substitution of Tl by Hg leads to the structurally analogous $\text{Hg-}12(n-1)n$ counterparts. The lattice parameters of selected cuprate superconductors are listed in Table 52.4.

52.2.4 Critical Temperatures

Next, some of the factors determining the critical temperature of cuprate superconductors will be discussed. As shown in the generic phase diagram for cuprate superconductors (Fig. 52.15), the critical temperatures of these materials are closely connected to the hole concentration p in the CuO_2 planes, which is determined by the formal valence $2 + p$ of the copper atoms in the conduction planes. Generally, an inverse parabolic dependence of the critical temperature on the number of holes per CuO_2 has been found. The maximum T_c is typically reached for a hole concentration p of 0.15–0.2 holes per CuO_2 . For hole concentrations above 0.2 holes per CuO_2 the critical temperature decreases with increasing carrier concentration, leading to a non-superconducting metal for $p > 0.3$ holes per CuO_2 . As an example of this behaviour the critical temperature of $\text{HgBa}_2\text{CuO}_{4+\delta}$ as function of the hole concentration is shown in Fig. 52.20.

^a Using a pseudo-tetragonal unit cell a lattice parameter $a(\text{tetragonal}) \cong (a + b)/2\sqrt{2} \approx 0.38 \text{ nm}$ would result

Fig. 52.20 Critical temperature of HgBa₂CuO_{4+δ} versus hole concentration. The maximum critical temperature is reached for a hole concentration of 0.18 holes/CuO₂ (After [52.31] p. 123)

In addition to the carrier concentration, the number of CuO₂ planes in the perovskite blocks is of importance for the critical temperature. The maximum critical temperatures of selected cuprate superconductors listed in Table 52.5 clearly indicate that the critical

Fig. 52.21 Critical temperature of Hg-12(*n* − 1)*n* superconductors versus the number *n* of CuO₂ planes in the perovskite (copper oxide) blocks (After [52.48])

temperature increases with increasing number *n* of CuO₂ planes in the copper oxide blocks, at least up to the compound with *n* = 3. For compounds with four or more CuO₂ planes in the perovskite blocks,

the critical temperature decreases with increasing n . In Fig. 52.21, this behaviour is illustrated for the Hg-12($n-1$) n compounds. A possible explanation for the observed behaviour is the fact that in cuprates with $n \geq 3$ the hole concentrations in the central and outer CuO₂ layers may be considerably different. It may therefore be impossible to reach simultaneously the optimum carrier concentration in all the CuO₂ layers for compounds with $n \geq 4$.

Finally, it should be mentioned that the critical temperature of cuprate superconductors has been found to be

connected with the lattice parameters. Consequently, the critical temperature depends on applied pressure. Application of a hydrostatic pressure typically enhances the critical temperature of cuprate superconductors. In Hg-1223, superconductivity was observed at temperatures as high as 164 K at a pressure of 31 GPa [52.49]. A more complex situation results for the application of uniaxial pressure. In the case of pressure along the crystallographic a - or b -axis the critical temperature is enhanced, whereas for uniaxial pressure along the c -direction T_c is reduced [52.50, 51].

52.3 Physical Properties of Cuprate Superconductors

52.3.1 Anisotropic Superconductors

As a consequence of the layered crystal structures of the cuprates, the penetration depth depends on the direction of the screening currents. Assuming that the screening currents in the a - and b -direction are equal, two different penetration depths λ_{ab} and λ_c result. The indices give the direction of the screening currents. Thus, two different Ginzburg–Landau parameters $\kappa_{ab}(B||ab)$ and $\kappa_c(B||c)$ can be defined

$$\kappa_{ab} = \left(\frac{\lambda_{ab}\lambda_c}{\xi_{ab}\xi_c} \right)^{1/2}, \quad (52.20)$$

$$\kappa_c = \frac{\lambda_{ab}}{\xi_{ab}},$$

where ξ_{ab} and ξ_c are the coherence lengths in the ab -plane and along the c -direction respectively. The

Table 52.5 Critical temperatures of optimally doped cuprate superconductors

Compound	n	T_c (K)	Reference
Y-123	2	92	[52.20]

dimensionless anisotropy parameter is given by [52.56]

$$\gamma_a = \left(\frac{m_c}{m_{ab}} \right)^{1/2} = \frac{\lambda_c}{\lambda_{ab}} = \frac{\xi_{ab}}{\xi_c} = \frac{B_{c2,ab}}{B_{c2,c}} = \frac{B_{c1,c}}{B_{c1,ab}} \quad (52.21)$$

where m_{ab} and m_c are the effective masses of the charge carriers for in-plane and out-of-plane currents, respectively. The expressions for the upper critical fields are [52.40, 56]

$$B_{c2,c} = \frac{\phi_0}{2\pi\xi_{ab}^2}$$

$$B_{c2,ab} = \frac{\phi_0}{2\pi\xi_c\xi_{ab}} \quad (52.22)$$

The upper and lower critical fields of various cuprate superconductors are listed in Table 52.6. The lower critical fields are typically between 10 and 500 mT for magnetic fields applied along the c -direction. The upper critical fields of cuprate superconductors can exceed 100 T even for the unfavourable field direction $B||c$. The data for Tl-2201, Hg-1201 and Hg, Cu-1201 given in Table 52.6 clearly indicate that the critical fields, like the critical temperatures, depend on the actual doping level.

For the characteristic length scales in cuprate superconductors the following relation has been found

$$\xi_c < \xi_{ab} \ll \lambda_{ab} < \lambda_c. \quad (52.23)$$

Table 52.7 lists for various cuprate superconductors the penetration depths and the coherence lengths. The in-plane coherence length ξ_{ab} is typically 1–4 nm. The considerably smaller values found for the out-of-plane coherence length ξ_c are comparable to interatomic distances. The small values of ξ_c are responsible for the insulating character of the charge-carrier reservoirs (Fig. 52.14) separating adjacent CuO₂ blocks. The

cuprates are therefore nearly two-dimensional superconductors with intrinsic Josephson junctions along the *c*-direction. Moreover, the cuprates are extreme type II superconductors with κ_c values around 100.

52.3.2 Irreversibility Line

The magnetic phase diagram of cuprate superconductors is much more complicated than that of metallic superconductors. It is beyond the scope of this chapter to describe the details of the magnetic phase diagram of cuprate superconductors. A simplified magnetic phase diagram is shown in Fig. 52.22. An outstanding feature of high-temperature superconductors is the existence of an irreversibility line well below the upper critical field. Above this line the vortices are movable, and hence the critical current density is zero. The irreversibility line can be described by the expression

$$B_{irr} = B_0 \left(1 - \frac{T_{irr}}{T_c}\right)^\alpha$$

(52.24)

Fig. 52.22 Simplified magnetic phase diagram of cuprate superconductors. Above the irreversibility line the vortices are movable, and hence the critical current density is zero (After [52.31] p. 138)

where B_{irr} is the irreversibility field, T_{irr} the irreversibility temperature, B_0 a fitting parameter and the exponent

α is characteristic of the superconductor in question. In the case of Y-123 the exponent α is close to 1.5 for magnetic fields perpendicular to the crystallographic c -direction, while values around 1.3 have been found for $B||c$ [52.61].

The existence of the irreversibility line is reflected in the broadening of the resistive transition in the presence of an applied magnetic field. Figure 52.23 shows the resistive transition of a Bi-2212 single crystal for magnetic

Fig. 52.23 Resistivity versus temperature curves of a Bi-2212 single crystal for magnetic fields parallel to the c -direction ([52.31] p. 139)

fields of 2, 5 and 12 T parallel to the c -direction. The data for zero applied field are also shown in Fig. 52.23. The end point of the resistive transition corresponds to the irreversibility temperature for the magnetic field applied. On the other hand, the onset of the resistivity drop may be used to determine the upper critical field.

The existence of an irreversibility line can be explained in two different ways. In the more conventional picture the occurrence of resistance above the irreversibility line is caused by thermally activated depinning. Within this picture it can be easily understood that the irreversibility line of cuprate superconductors is shifted to higher fields and temperatures by heavy-ion irradiation [52.77–79]. The irradiation generates amorphous tracks, which are efficient pinning centres. An alternative scenario is the melting of the flux-line lattice. Evidence for this possibility is the latent heat measured at the phase transition [52.80, 81].

The maximum operating field of cuprate superconductors is limited by the irreversibility line for the unfavourable field direction $B||c$. In any comparison of the behaviour of different cuprates the irreversibility field as a function of the reduced temperature T/T_c should be considered. The highest irreversibility fields result for Y-123, while the lowest values of B_{irr} have been found for Bi- and Tl-22($n-1$) n compounds. Intermediate irreversibility fields result for Tl- and Hg-12($n-1$) n compounds [52.31, 82]. The observed order in the irreversibility fields indicates that flux pinning is more efficient in cuprates with less anisotropic physical properties. The largest anisotropy of the physical properties has been observed in Bi- and Tl-22($n-1$) n compounds with the largest distance of adjacent CuO_2 blocks. The relatively small anisotropy of Y-123 seems to be the consequence of the short-circuiting of the insulating charge-carrier reservoirs by the CuO chains (Fig. 52.18).

52.3.3 Limitations of the Transport Critical Current

The electric field generated in a superconductor at the transition to the normal conducting state is typically well described by a power law $E = E_c(I/I_c)^n$, where I is the current, n is the index of resistive transition and E_c the electric field used to define the critical current I_c . Typically E_c values of 0.1 or 1 $\mu\text{V}/\text{cm}$ are used to determine the critical current.

It should be recognised that, unlike the critical temperature and the upper critical field, the critical current density is not an intrinsic material property. The

Fig. 52.24 Critical current densities in epitaxial Bi-2212 films as a function of applied magnetic field for B along the ab -planes and parallel to the crystallographic c -direction (After [52.83])

achievable j_c values are determined mainly by the microstructure of the superconductor in question. Grain boundaries can act as weak links, leading to small critical current densities in polycrystalline cuprate superconductors. In the absence of grain-boundary weak links, the transport j_c is mainly determined by flux pinning. Before these effects are discussed the anisotropy of j_c in individual grains and epitaxial thin films is considered.

Anisotropy of the Critical Current Density

In cuprate superconductors, conductive copper oxide blocks and insulating charge-carrier reservoirs alternate along the crystallographic c -direction. The currents can easily flow in the conductive CuO_2 planes, whereas currents along the c -direction have to cross the insulating or semiconducting charge carrier reservoirs (tunnelling). In spite of j_c values as high as 10^8 A/cm^2 in the CuO_2 planes of Hg-1212 films, the estimated j_c along the c -direction is as low as 5000 A/cm^2 [52.84].

A further anisotropy of the critical current density is related to the direction of the applied magnetic field. Figure 52.24 shows the critical current density of an epitaxial Bi-2212 film as a function of the applied magnetic field for selected temperatures. The critical current density declines rapidly with increasing applied field for $B \parallel c$, while the field dependence of j_c is much less pronounced for $B \parallel ab$. This behaviour reflects the considerably different upper critical fields for these two

field directions. The angle dependence of j_c in epitaxial Bi-2212 and Bi-2223 films can be described by the expression

$$j_c(B, \theta) = j_{c,c}(B \sin \theta), \quad (52.25)$$

where θ is the angle between the ab -planes and the field direction, and $j_{c,c}$ is the critical current density for $B \parallel c$. The above expression states that the reduction of the critical current by an applied magnetic field is determined exclusively by the field component parallel to the c -direction.

Grain-Boundary Weak Links

Soon after the discovery of superconductivity above 77 K in Y-123, it was noticed that the transport j_c in sintered samples is typically well below 1000 A/cm^2 . In addition, magnetic fields of a few mT are sufficient to reduce the j_c by an order of magnitude. On the other hand, critical current densities well above 10^6 A/cm^2 could be achieved in epitaxial Y-123 films. These experimental results suggest that the grain boundaries present in polycrystalline material can act as barriers for the transport current. Due to extremely short coherence lengths $\xi_c < 1 \text{ nm}$ the Cooper pair density can be considerably reduced within the width of a grain boundary. Two grains separated by a grain boundary can therefore be considered as a Josephson junction.

The high j_c values achieved in highly textured films suggest that low-angle grain boundaries are strongly coupled. To clarify this aspect, the transport properties of artificial grain boundaries have been studied [52.85,86]. In epitaxial growth the crystallography prescribed by the substrate can be transmitted to the Y-123 film. Using SrTiO_3 bicrystals, two Y-123 grains connected by an artificial grain boundary with a well defined misorientation angle θ can be prepared. The critical current density across the grain boundaries has been found to decrease rapidly with increasing misalignment angle. For [001]-tilt boundaries (rotation of the second grain around the common c -axis) in Y-123 films, the grain boundary j_c depends exponentially on the misalignment angle θ

$$j_c = j_{c0} \exp\left(-\frac{\theta}{\theta_0}\right), \quad (52.26)$$

where $\theta_0 \cong 6.3^\circ$ and $j_{c0} \cong 2 \times 10^7 \text{ A/cm}^2$ at 4.2 K [52.87]. The corresponding values for Bi-2223 [001]-tilt grain boundaries are $j_{c0} = 6 \times 10^6 \text{ A/cm}^2$ and $\theta_0 = 5^\circ$ at 26 K [52.88].

The weak-link behaviour is closely related to the strong reduction of the Cooper pair density in the grain

Fig. 52.25 Space charge effects and band bending at a semiconductor–metal interface (*top*) and at a grain boundary in a cuprate superconductor (*bottom*) (After [52.90])

boundaries caused by the extremely short coherence lengths and the low carrier concentrations in cuprate superconductors. The carrier concentration in optimally doped cuprate superconductors is around $5 \times 10^{21} \text{ cm}^{-3}$, whereas the carrier concentration in copper is as high as $85 \times 10^{21} \text{ cm}^{-3}$. Furthermore, the behaviour of grain boundaries in cuprate superconductors is similar to that of semiconductor–metal interfaces [52.89, 90]. In the case of a p-type semiconductor in contact with a metal characterised by a smaller work function, electrons flow from the metal into the semiconductor. As a consequence, both the valence and the conduction band are bent downwards (see Fig. 52.25 *top*). There results an excess of negatively charged acceptor ions and a depletion of holes in the valence band. Currents from the metal to the semiconductor would further enlarge the space-charge region and are therefore negligible (Schottky contact). Because of low carrier concentrations and

Fig. 52.26 Critical temperature (Δ) and current density (○) of a symmetric 24° [001]-tilt boundary as a function of the hole concentration. The charge-carrier concentration in the bicrystalline $\text{Y}_{0.7}\text{Ca}_{0.3}\text{Ba}_2\text{Cu}_3\text{O}_{7-\delta}$ films has been modified by annealing at different oxygen pressures (After [52.87])

large dielectric constants ($\epsilon \approx 10$), band-bending effects can occur in cuprate superconductors. The grain boundaries of cuprate superconductors may be considered as double Schottky barriers (see Fig. 52.25 *bottom*). The resulting Thomas–Fermi screening length is in the range of 0.5–1 nm, which is comparable to the coherence length. The width of the insulating layer at the grain boundary is $t = d + 2l_d$, where d is the structural width of the boundary and l_d the thickness of the depletion layer. The structural width of typical grain boundaries is $\approx 0.4 \text{ nm}$. On the other hand, the thickness of the depletion layer is 0.16 nm for $\epsilon = 10$, an in-built voltage of 0.1 V and a carrier concentration of $4.5 \times 10^{21} \text{ cm}^{-3}$ [52.90]. Consequently, the total thickness of the insulating layer is considerably enhanced by the space-charge region.

In such a scenario it should be possible to modify the electronic properties of the interface by increasing the carrier concentration. In Y-123 this can be done by Ca doping. Figure 52.26 shows for symmetric 24° [001]-tilt boundaries the critical temperature and current density as a function of the hole concentration. As expected the j_c values at 4.2 K increase with increasing hole concentration even in the overdoped region, where T_c decreases.

Flux Pinning

Transport currents without losses can flow in a type II superconductor only when the flux lines are effectively

pinned. The screening currents circulating around each flux line are responsible for a repulsive vortex–vortex interaction, which prevents flux motion as soon as a sufficiently large fraction of the flux lines is pinned. The effectiveness of this collective pinning depends on the stiffness of the flux-line lattice.

The energy required to create a flux line can be estimated from the lower critical field B_{c1} [52.39]. At the lower critical field, flux lines start to enter the superconductor. The formation energy for each flux line is therefore

$$E_{fl} = \int_0^{B_{c1}} m dB \quad \text{with} \quad m = \frac{\phi_0}{\mu_0} l_{fl}, \quad (52.27)$$

where m is the magnetic moment of a flux line of length l_{fl} containing a single flux quantum. The required energy per unit length is

$$\frac{E_{fl}}{l_{fl}} = \frac{\phi_0}{\mu_0} B_{c1}. \quad (52.28)$$

Using $\kappa = \lambda_L/\xi$ the lower critical field can be written as [52.34]

$$B_{c1} = \frac{\phi_0 \ln \kappa}{4\pi\lambda_L^2}. \quad (52.29)$$

When the flux line is in a normal region, no energy is required to form the normal vortex core, and the resulting

pinning energy per unit length is

$$\frac{E_{fl}}{l_{fl}} = \frac{1}{4\pi\mu_0} \left(\frac{\phi_0}{\lambda_L} \right)^2 \ln \left(\frac{\lambda_L}{\xi} \right). \quad (52.30)$$

Generally regions with reduced Cooper pair densities due to defects can act as pinning centres.

The pinning properties of the cuprate superconductors are highly anisotropic. Relatively strong pinning has been found for magnetic fields transverse to the current direction applied in the ab plane. For the resulting Lorentz force along the c -direction, strong intrinsic pinning may be provided by the insulating charge carrier reservoirs of the layered structure along the c -direction. On the other hand, the pinning is weak for magnetic fields transverse to the current direction applied along the c -direction, leading to a Lorentz force parallel to the ab -planes. Flux lines along the c -direction experience strong pinning only within the CuO_2 blocks. As a consequence of the layered structure, the vortices may be cut into vortex segments or even pancake vortices which exist only within the conductive CuO_2 blocks. These pancake vortices could easily move in the direction of the Lorentz force.

The positions of the irreversibility lines in the different cuprate superconductors reflect the anisotropy of the pinning properties. Typically the pinning efficiency for magnetic fields along the c -direction decreases as one progresses from Y-123 via the Hg- and Tl- $12(n-1)n$ compounds to the highly anisotropic Bi- and Tl- $22(n-1)n$ cuprates.

52.4 Superconducting Films

Because of the weakly coupled large-angle grain boundaries present in polycrystalline bulk material, the transport critical current density is much smaller than the j_c of the individual grains. In contrast to polycrystalline bulk material, adjacent grains of epitaxial films are connected by low-angle grain boundaries. As a consequence the critical current densities measured in epitaxial films are close to the j_c values of individual grains. At low temperatures and zero applied field, the critical current densities in epitaxial Y-123, Bi-2212, Bi-2223 and Hg-1223 films exceed 10^7 A/cm^2 [52.83, 91–93]. Even at 77 K j_c -values well above 10^7 A/cm^2 have been measured in Y-123 films [52.94].

The physical properties of ultrathin films can be considerably different from those of bulk single crystals.

First, let us consider the effect of the film thickness on the critical temperature. For the growth of epitaxial ultrathin films a substrate with good lattice matching is required. $\text{YBa}_2\text{Cu}_3\text{O}_7$ films of thickness equal to the height of a single unit cell in the c -direction can be grown onto SrTiO_3 single crystals covered by a six-unit-cell-thick non-superconducting $\text{PrBa}_2\text{Cu}_3\text{O}_7$ (Pr-123) buffer layer [52.95]. The lattice mismatch of Y-123 and Pr-123 is less than 1.5%. The layer growth can be checked by the observation of the strong intensity oscillations of reflection high-energy electron diffraction. The period of these oscillations has been found to correspond to the height of a single unit cell. Y-123 films with a thickness of 1–10 unit cell heights were grown by coevaporation of the metals under oxygen atmosphere.

Fig. 52.27 Offset critical temperature of ultra-thin Y-123 films as a function of the layer thickness normalised to the c lattice parameter (After [52.95])

To provide hole doping the ultrathin Y-123 films are covered by a six-unit-cell-thick Pr-123 layer. The offset critical temperature of these Y-123 films is considerably lower than that of a 100-nm-thick film (Fig. 52.27). On the other hand, the onset critical temperature has been found to be much less affected. The reduction of the offset critical temperature has been attributed to the more pronounced critical fluctuations in the thinner films. Critical fluctuations are variations of the superconducting order parameter $\psi = n_C^{1/2} \exp(i\varphi)$ (n_C is the Cooper pair density) around the thermal equilibrium values.

The critical temperature of ultrathin Y-123 layers in Y-123/Pr-123 multilayers has been found to depend on the thicknesses of the insulating Pr-123 layers [52.96]. The thickness of 1.2 nm of the embedded Y-123 layers corresponds to the height of a single unit cell in the c -direction. The critical temperature of the Y-123/Pr-123 multilayer decreases from ≈ 50 K (10% of normal-state resistance) to ≈ 13 K for Pr-123 interlayer thicknesses of 1.2 and 7.2 nm, respectively. Because of the Josephson coupling of adjacent Y-123 layers in the multilayer the critical fluctuations are expected to be less pronounced than in a single Y-123 film of the same thickness. Thus, the T_c of the Y-123 layers in the Y-123/Pr-123 multilayer with a Pr-123 thickness of 1.2 nm is higher than that of a single Y-123 layer of the same thickness (Fig. 52.27).

Fig. 52.28 Resistivity versus temperature for La-214 films on SrTiO₃ and SrLaAlO₄ substrates. The different epitaxial strains lead to considerably different critical temperatures of 10 and 49 K. For comparison the resistivity of La-214 bulk material ($T_c = 25$ K) is also shown (After [52.51])

Finally, let us consider the effects of epitaxial strain on the critical temperature of (La, Sr)₂CuO₄ films [52.51, 97, 98]. In epitaxial growth the crystallography prescribed by the substrate is transmitted to the film. For a sufficiently small film thickness the lattice constant of the film is equal to that of the substrate. As a consequence of the lattice mismatch a considerable epitaxial strain can be induced in the film. Under epitaxial growth conditions a compressive strain in the CuO₂ planes of (La, Sr)₂CuO₄ is accompanied by a tensile strain in the c -direction. Typically, in-plane compressive and out-of-plane tensile strains enhance the T_c of cuprate superconductors. Thus, the critical temperature of cuprate superconductors should be much more sensitive to epitaxial strain effects than to hydrostatic pressure, where the opposite in-plane and out-of-plane effects partly cancel each other. Because of film deposition at temperatures above 750 °C, differences in the thermal expansion coefficients provide an additional contribution to the strain in the films. In thick films the epitaxial strain is released by the appearance of misfit dislocations. The expected change in the critical temperature of the films is given by

$$T_c = T_c(0) + 2 \frac{dT_c}{d\varepsilon_{ab}} \varepsilon_{ab} + \frac{dT_c}{d\varepsilon_c} \varepsilon_c, \quad (52.31)$$

where $\varepsilon = (d_{\text{bulk}} - d_{\text{strained}})/d_{\text{bulk}}$, with d a lattice parameter.

To study the epitaxial strain effects, Locquet et al. deposited $\text{La}_{1.9}\text{Sr}_{0.1}\text{CuO}_4$ films ($a = 0.3784 \text{ nm}$, $\alpha = 8.5 \times 10^{-6} \text{ K}^{-1}$) of 10–15 nm thickness on SrTiO_3 ($a = 0.3905 \text{ nm}$, $\alpha = 9 \times 10^{-6} \text{ K}^{-1}$) and SrLaAlO_4 ($a = 0.3754 \text{ nm}$, $\alpha = 10.5 \times 10^{-6} \text{ K}^{-1}$) substrates. Using X-ray diffraction, strain values of $\varepsilon_{ab} = 0.63\%$ and $\varepsilon_c = -0.76\%$ have been determined for the La-214 film on SrTiO_3 . The corresponding strain values for the La-214 film deposited onto SrLaAlO_4 are $\varepsilon_{ab} = -0.54\%$ and $\varepsilon_c = 0.35\%$. The results of Locquet et al. are

shown in Fig. 52.28. The critical temperatures of the La-214 films of 10 (SrTiO_3) and 49 K (SrLaAlO_4) are, as expected, considerably different from the bulk value of 25 K. In addition, the temperature dependencies of the normal state resistivities of the two films are remarkably different. The film experiencing a tensile in-plane strain shows an upturn of the normal state resistance at temperatures below 100 K, which is an effect also found in underdoped cuprate superconductors.

52.5 The Special Case of MgB_2

In spite of the fact that MgB_2 has been known since the early 1950s, it was unknown until 2001 that it is a superconductor with a remarkably high transition temperature. Figure 52.29 shows the hexagonal crystal structure of MgB_2 , consisting of alternating layers of boron and magnesium. As a consequence of the layered structure, anisotropic physical properties result. The arrangement of the boron atoms is the same as that of the carbon atoms in graphite. Each of the boron atoms is surrounded by three other boron atoms at the same distance.

To study the role of phonons in the superconductivity of MgB_2 , the critical temperatures of isotopically pure Mg^{10}B_2 and Mg^{11}B_2 specimens have been studied [52.99]. The transition temperatures of Mg^{11}B_2 and Mg^{10}B_2 defined by a 2% onset criterion are 39.2 and

40.2 K, respectively. Defining a partial boron isotope-effect exponent $\beta_B = \Delta \ln T_c / \Delta \ln M_B$, where M_B is the atomic mass of boron, a value of $\beta_B = 0.26 \pm 0.03$ results from the experimental data. On the other hand, the isotope effect for $^{26}\text{MgB}_2$ and $^{24}\text{MgB}_2$ is much less pronounced [52.100]. The shift of 0.1 K in T_c corresponds to a partial Mg isotope-effect exponent β_{Mg} of 0.02. The strong boron isotope effect suggests that the pairing of the electrons is caused by the boron phonons. Thus, MgB_2 seems to be a conventional metallic superconductor with an extremely high transition temperature. The high transition temperature seems to be caused by the small atomic mass of boron, leading to high phonon frequencies.

The currently known physical properties of MgB_2 are summarised in Table 52.8. As in cuprate superconductors the operation range of MgB_2 is limited by the irreversibility field. In polycrystalline bulk samples the irreversibility field typically reaches 50% of B_{c2} . In nanocrystalline MgB_2 bulk material the irreversibility field is shifted to 80% of B_{c2} . The enhancement of the irreversibility field in the nanocrystalline material has been attributed to the improved pinning provided by the large number of grain boundaries [52.101]. Maximum irreversibility fields of more than 14 T at 4.2 K have been reported for MgB_2 bulk material annealed in Mg vapour [52.102]. MgB_2 is an extreme type II superconductor with a Ginzburg–Landau parameter κ of 38. The coherence length of $\xi_c \approx 2.5 \text{ nm}$ is considerably larger than the values of $\approx 0.2 \text{ nm}$ measured for cuprate superconductors (Table 52.7). The anisotropy of the upper critical fields reported for c -axis-oriented films [52.103] and single crystals [52.104] is typically close to $B_{c2,ab}/B_{c2,c} \approx 3$.

Immediately after the discovery of superconductivity in MgB_2 the current transport across grain boundaries

Fig. 52.29 Hexagonal crystal structure of MgB_2 consisting of alternating layers of magnesium and boron (After [52.15])

Table 52.8 Physical properties of MgB₂

Parameter	Value	Comments	Reference
T_c (K)	40.2	Mg ¹⁰ B ₂	[52.99]

λ (nm)	110–180	$T = 0$	[52.107, 111]
$\kappa = \lambda/\chi$	38	polycrystalline, $T = 0$	[52.107]
2Δ (meV)	17–19*	$T = 4.2\text{ K}$	[52.112]

* MgB₂ seems to be a double gap superconductor (see for example [52.113])

was studied [52.105, 106]. The results of these investigations indicate that the grain boundaries in MgB₂ do not act as weak links. This behaviour reflects the fact that the coherence length of MgB₂ is considerably larger than that of cuprate superconductors.

To give an impression of the current-carrying capacity of MgB₂ the critical current density of c -axis-oriented films as a function of temperature is shown in Fig. 52.30 for selected applied magnetic fields ($B||c$). The critical current density at 15 K and zero applied field is as high as 16 MA/cm² [52.114, 115], which is comparable to the j_c values of cuprate superconductors.

Finally, let us briefly consider the synthesis of MgB₂. Polycrystalline MgB₂ can be synthesised by the reaction of boron powder with magnesium vapour. Stoichiometric quantities of boron and magnesium are sealed into a tantalum tube under an argon atmosphere. In addition, the tantalum tube containing the B/Mg mixture is sealed into a quartz ampoule. To form the desired MgB₂ intermetallic compound the mixture is heat treated at 950 °C for 2 h [52.116]. In a similar way boron precursor films can be converted to MgB₂ in the presence of Mg vapour. The annealing temperature for the formation of MgB₂ films is typically in the 850 °C range. Very recently c -axis-oriented epitaxial MgB₂ films have been grown onto Al₂O₃ substrates [52.103]. For applications in electronics it is

Fig. 52.30 Critical current density of a c -axis-oriented MgB₂ film as a function of temperature for magnetic fields up to 4 T (After [52.114])

desirable to grow the MgB₂ films in situ in a single step on a suitable substrate. The substrate and electronic materials ZrO₂, MgO, TiN, TaN, AlN and SiC show no reaction with MgB₂ up to an annealing temperature of 800 °C [52.117].

52.6 Summary

The cuprate high-temperature superconductors are characterised by layered crystal structures. Conductive CuO₂ layers in the crystallographic *ab*-planes are a common feature of all cuprate superconductors. Along the *c*-direction, conducting copper oxide blocks and insulating charge-carrier reservoirs alternate. As a consequence the physical properties of cuprate superconductors are strongly anisotropic.

The critical temperature as well as the other physical properties depend considerably on the charge-carrier concentration. The maximum critical temperature is typically reached for a carrier concentration of 0.18 holes per CuO₂. Furthermore, the highest T_c of optimally doped cuprate superconductors is typically reached in compounds with three or four CuO₂ layers in the CuO₂ blocks. The highest known critical temperature of 135 K at ambient pressure has been achieved in Hg-1223.

The cuprate superconductors are close to a metal–insulator transition. The d-wave symmetry of the energy gap and the existence of a pseudogap above T_c , especially in underdoped cuprate superconductors, suggest that the pairing mechanism of the electrons is different from that in metallic superconductors. Furthermore,

only a weak isotope effect has been observed in the cuprates, which again suggests that the electron pairing is not phonon-mediated.

Extremely short coherence lengths and low carrier concentrations seem to be responsible for the weak-link behaviour of large-angle grain boundaries in the cuprate superconductors. To achieve transport critical current densities comparable to the intra-grain j_c a biaxial texture is required.

The recently discovered metallic superconductor MgB₂ may be interesting for applications in spite of the moderate critical temperature of 39 K because of a simpler chemistry and the fact that grain boundaries do not act as weak links. The observation of a pronounced boron isotope effect suggests that MgB₂ is a conventional BCS superconductor. The anisotropy of the physical properties of MgB₂ is less pronounced than that of the cuprate superconductors.

The maximum operation fields of both the cuprate superconductors and MgB₂ are limited by the irreversibility line, which is well below the upper critical field. The existence of an irreversibility line may be caused in both types of materials by thermally activated depinning or flux-line lattice melting.

Molecular Ele

53. Molecular Electronics

The prospects of using organic materials in electronics and optoelectronics applications have attracted scientists and technologists since the 1970s. This field has become known as **molecular electronics**. Some successes have already been achieved, for example the liquid-crystal display. Other products such as organic light-emitting displays, chemical sensors and plastic transistors are developing fast. There is also a keen interest in exploiting technologies at the molecular scale that might eventually replace silicon devices. This chapter provides some of the background physics and chemistry to the interdisciplinary subject of molecular electronics. A review of some of the possible application areas for organic materials is presented and some speculation is provided regarding future directions.

Molecular electronics is concerned with the exploitation of organic and biological materials in electronics and optoelectronics [53.1–3]. The subject, as it has matured over the last 30 years, can broadly be divided into two themes. The first area, *molecular materials for electronics*, has its origins in materials science and concerns the development of devices that utilise the unique macroscopic properties of organic compounds. The most successful commercial product to date is the liquid-crystal display. However, following many years of research, devices such as organic light-emitting displays, pyroelectric detectors for infrared imaging, and chemical and biochemical sensors are beginning to make a technological impact. The Nobel prize in Chemistry for 2000 was awarded to three scientists working in this area: Alan Heeger, Alan MacDiarmid and Hideki Shirakawa, who have made significant contributions to the development of electrically conductive polymers. More challenging is *molecular-scale electronics*. Here, the focus is on the behaviour of individual organic molecules or groups of molecules. Topics such as molecular switches [53.3–9], molecular memories [53.10–13], mo-

lecular rectifiers [53.14], negative differential-resistance junctions [53.15], deoxyribonucleic acid (DNA) electronics [53.16] and molecular manufacturing [53.17, 18] have all been described in the literature. It is much too early to say which, if any, of these could find their way into the commercial arena.

This chapter provides an introduction to the interdisciplinary world of molecular electronics. In the first instance, the physics background to semiconductive organic compounds is outlined. A review of the available materials is presented and some of the possible device applications are described. There are currently a limited number of ways in which organic molecules can be deposited and manipulated on surfaces to form solid films, which can then be used in device structures. The most popular methods are outlined, and methods to pattern the films are described. The prospects for molecular-scale electronics are contrasted with the progress of the inorganic semiconductor industry. Finally, a selection of the ongoing work on molecular-scale devices is described and some speculation about future developments is given.

53.1 Electrically Conductive Organic Compounds

Metallic and semiconductive behaviour is not restricted to inorganic materials. Figure 53.1 shows that the room-temperature conductivity values for organic polymers can extend over much of the spectrum of electrical conductivity, from insulating to semiconducting, and even metallic, behavior [53.19]. The physical explanation can be found in the nature of the chemical bonds that hold solids together.

53.1.1 Orbitals and Chemical Bonding

Carbon-based materials are unique in many respects. This is due to the many possible configurations of the electronic states of a carbon atom. Carbon has an atomic number of six and a valency of four. Its electron configuration is $1s^2, 2s^2, 2p^2$, i. e. the inner $1s$ shell is filled and the four valence electrons available for bonding are distributed two in the $2s$ orbital and two in the $2p$ orbitals. As the $2s$ orbital is spherically symmetrical, Fig. 53.2, it can form a bond in any direction. In contrast, the $2p$ orbitals are directed along mutually orthogonal axes and will tend to form bonds in these directions. When two or more of the valence electrons of carbon are involved in bonding with other atoms, the bonding can be explained by the construction of *hybrid* orbitals by mathematically combining the $2s$ and $2p$ orbitals. In the simplest

case, the carbon $2s$ orbital hybridises with a single p orbital. Taking the sum and difference of the two orbitals gives two sp *hybrids*; two p orbitals then remain. The sp orbitals are constructed from equal amounts of s and p orbitals; they are linear and 180° apart.

Other combinations of orbitals lead to different hybrids. For example, from the $2s$ orbital and two $2p$ orbitals (e.g. a $2p_x$ and a $2p_y$), three equivalent sp^2 hybrids may be constructed. Each orbital is 33.3% s and 66.7% p . The three hybrids lie in the xy plane (the same plane defined by the two p orbitals), directed 120° from each other, and the remaining p orbital is perpendicular to the sp^2 plane. Four sp^3 hybrids may be derived from an s orbital and three p orbitals. These are directed to the corners of a tetrahedron with an angle between the bonds of 109.5° ; each orbital is 25% s and 75% p .

A chemical bond can also be formed from a mixture of the above hybrid orbitals, e.g. it is possible to have a hybridised orbital that is 23% s and 77% p . Thus, sp , sp^2 and sp^3 hybrids must be considered as limiting cases. Electrons in s orbitals have a lower energy than electrons in p orbitals. Therefore, bonds with more s character tend to be stronger.

Carbon forms four bonds in most compounds, resulting from its four valence electrons. In ethane, C_2H_6 , the C–H bonds are all approximately $C(sp^3)-H(s)$ while the C–C bond is approximately $C(sp^3)-C(sp^3)$. However, in the ethylene molecule, C_2H_4 , each of the two carbons is attached to just three atoms while in acetylene, C_2H_2 , each carbon atom is only attached to one carbon. In these compounds, the two carbon atoms are bound together by double ($CH_2=CH_2$) or triple ($CH\equiv CH$) bonds, which involve sp^2 and sp hybrids, respectively. These bonds can be considered to have two distinct components. For example, in ethylene, two sp^2 hybrids on each carbon bond with the hydrogens. A third sp^2 hy-

Fig. 53.3 Sigma (σ) and pi (π) bonding

brid on each carbon forms a $C(sp^2)-C(sp^2)$ single bond, leaving a p orbital 'left-over' on each carbon. This orbital lies perpendicular to the plane of the six atoms. The two p orbitals are parallel to each other and have regions of overlap above and below the molecular plane. This type of bond, consisting of two separate sausage-like electron clouds lying above and below the planes of the carbon nuclei, is called a pi (π) bond. In contrast, the bond formed by the head-on overlap of the two carbon sp^2 orbitals is known as a sigma (σ) bond and the electron cloud is densest at the midpoint between the carbon nuclei. The π bond has little electron density in the region between the carbon atoms and is much weaker than the σ bond. Figure 53.3 illustrates sigma and pi bonding. Carbon compounds that contain π bonds are said to be unsaturated, meaning that the carbon atoms, while having formed the requisite number of bonds, are not fully saturated in terms of their number of potential neighbours. Saturated carbon molecules, on the other hand, contain only single bonds.

53.1.2 Band Theory

The application of quantum mechanics to the electrons in the bonds of inorganic semiconductors led to the development of band theory, one of the great success stories of modern physics. Whenever two identical atoms are brought close together, the electron orbitals overlap and the energy level associated with each electron in the separated atoms is split into two new levels, with one above and one below the original level. A rigorous, quantum-mechanical description of the bonding reveals that the total number of orbitals must be conserved, i. e. the total number of molecular orbitals must be the same as the number of atomic orbitals that went into their formation. Consider, for example, the formation of a hydrogen molecule from two separated atoms. When the two atoms approach each other so that their 1s orbitals overlap, two new orbitals (σ bonds) are formed around the atoms, symmetric with respect to the interatomic axis. In one

orbital, the bonding orbital, the electron has a lower energy than in the isolated atomic orbital and in the other, the antibonding orbital, an electron has a higher energy. In the hydrogen molecule, the electron pair normally resides in the bonding orbital. The energy of the electrons in this orbital is lowered relative to that in the atomic orbitals, which is why the atoms remain bound together.

In an extended solid many atoms can interact and many similar splittings of energy levels occur. For a solid containing approximately 10^{26} atoms (Avogadro's number) each energy level splits, but the energies between these split levels are very small and continuous ranges or bands of energy are formed. Two such important bands are the valence band and the conduction band, analogous to the bonding and antibonding levels of the two-atom model. The energy gap, or band gap, between them is a forbidden energy range for electrons. Electrical conduction takes place by electrons moving under the influence of an applied electric field in the conduction band and/or holes moving in the valence band. Holes are really vacancies in a band but, for convenience, they may be regarded as positively charged carriers. For an electron, or hole, to gain energy from an applied electric field, and therefore for conductivity to occur, the charge carrier must be able to move into an unoccupied higher energy state. If the carrier cannot be accelerated by the field, then it cannot contribute to the electrical conduction. In a metal, the various energy bands overlap to provide a single energy band that is only partly full of electrons. An insulator has a full valence band and a relatively large energy separation (> 5 eV) to the higher conduction band. Most semiconductors possess the band structure of an insulator, but a forbidden energy gap of only 0.1–3 eV, so that carriers may be produced in the conduction and/or valence bands by optical or thermal means, or by doping with impurities.

An important feature of the band model is that the electrons are delocalised or spread over the lattice. The strength of the interaction between the overlapping orbitals determines the extent of delocalisation that is possible for a given system. For many polymeric organic materials, the molecular orbitals responsible for bonding the carbon atoms of the chain together are the sp^3 hybridised σ bonds, which do not give rise to extensive overlapping. The resulting band gap is large, as the electrons involved in the bonding are strongly localised on the carbon atoms and cannot contribute to the conduction process. This is why a simple saturated polymer such as polyethylene, $(CH_2)_n$, is an electrical insulator.

A significant increase in the degree of electron delocalisation may be found in unsaturated polymers, i. e.

Fig. 53.4 (a) Chemical π bonding in polyacetylene. (b) Electronic band structure showing the normally empty π^* band (conduction band) and the normally filled π band (valence band)

those containing double and triple carbon–carbon bonds. If each carbon atom along the chain has only one other atom, e.g. hydrogen, attached to it, the spare electron in a p_z -orbital of the carbon atom overlaps with those of carbon atoms on either side forming delocalised molecular orbitals of π -symmetry. For a simple lattice of length $L = Na$, where N is the total number of atoms and a is the spacing between them, it can be shown that the total number of electron states in the lowest energy band is equal to N . This result is true for every energy band in the system and applies to three-dimensional lattices. Allowing for the two spin orientations of an electron, the Pauli exclusion principle requires that there will be room for two electrons per cell of the lattice in an energy band. If each atom contributes one bonding electron, the valence band will be only half filled.

It might therefore be expected that a linear polymer backbone consisting of many strongly interacting coplanar p_z orbitals, each of which contributes one electron to the resultant continuous π electron system, would behave as a one-dimensional metal with a half-filled band. In chemical terms, this is a conjugated chain and may be represented by a system of alternating single and double bonds. It turns out that, for one-dimensional systems, such a chain can more efficiently lower its energy by in-

roducing bond alternation (alternating short and long bonds). This limits the extent of electronic delocalisation that can take place along the backbone. The effect is to open an energy gap in the electronic structure of the polymer. All conjugated polymers are semiconductors, with band gaps more than about 1.5 eV, rather than metals (N.B. the band gap in silicon is 1.1 eV at room temperature). Figure 53.4 shows the chemical π bonding and the electronic band structure of polyacetylene.

53.1.3 Electrical Conductivity

In polyacetylene, the valence band, or π band, is normally filled with electrons while the conduction band, or π^* band is normally empty. Like silicon, the conductivity of polyacetylene can be changed by the addition of impurity atoms. However, the term *doping* is a misnomer as it tends to imply the use of minute quantities, parts per million or less, of impurities introduced into a crystal lattice. In the case of conductive polymers, typically 1% to 50% by weight of chemically oxidising (electron withdrawing) or reducing (electron donating) agents are used to alter physically the number of π -electrons on the polymer backbone, leaving oppositely charged counterions alongside the polymer chain. These processes are redox chemistry. For example, the halogen doping process that transforms polyacetylene to a good conductor is oxidation (or p-doping).

Reductive doping (n-doping) is also possible, e.g. using an alkali metal.

In both cases, the doped polymer is a salt. The counterions, I_3^- or Na^+ , are fixed in position while the charges on the polymer backbone are mobile and contribute to the conductivity. The doping effect can be achieved because a π electron can be removed (or added) without destroying the σ backbone of the polymer so that the charged polymer remains intact. The increase in conductivity can be as much as eleven orders of magnitude.

The electrical properties of semiconductive organic polymers are not directly comparable to those of silicon. An important material parameter is the mobility of the charge carriers μ . This determines the (additional) velocity that a charge carrier (an electron or hole) acquires because of an applied electric field, and is defined by

$$\mu = \frac{v_d}{E},$$

Table 53.1 Room-temperature field-effect carrier mobilities for field-effect transistors based on organic semiconductors [53.20,21]. The electron mobilities in single-crystal silicon and gallium arsenide are also given

Material	Mobility (cm^2/Vs)
Si single crystal (electrons)	1500
GaAs single crystal (electrons)	8500
Polythiophene	10^{-5}
Polyacetylene	10^{-4}
Phthalocyanine	$10^{-4} - 10^{-2}$
Thiophene oligomers	$10^{-4} - 10^{-1}$
Organometallic dmit complex	0.2
Pentacene	$10^{-3} - 1$
C_{60}	0.3

where v_d is the drift velocity of the carrier and E is the electric field. The mobility may be further related to the electrical conductivity σ by the expression

$$\sigma = |q|n\mu,$$

where n is the density of charge carriers and $|q|$ is the magnitude of their charge (charge on an electron $= 1.6 \times 10^{-19} \text{ C}$). The carrier mobility provides an indication of how quickly the carriers react to the field (i.e.

the frequency response of the material). The greater the degree of electron delocalisation, the larger the width of the bands (in energy terms) and the higher the mobility of the carriers within the band. For inorganic semiconductors such as silicon or gallium arsenide, the three-dimensional crystallographic structure provides for extensive carrier delocalisation throughout the solid, resulting in a relatively high mobility μ .

Electrical conduction in polymers not only requires carrier transport along the polymer chains but some kind of transfer, or *hopping*, between these chains, which tend to lie tangled up like a plate of spaghetti. The charge-carrier mobilities in organic polymers are therefore quite low, making it difficult to produce very high-speed electronic computational devices that are competitive with those based on silicon and gallium arsenide. However, some improvement in the carrier mobility can be achieved by both increasing the degree of order of the polymer chains and by improving the purity of the material. Table 53.1 contrasts the room-temperature carrier mobility values for Si, GaAs and a number of different conductive organic compounds [53.20,21]. Although the values are quite low for the organic materials, other features make them attractive for certain types of electronic device, as indicated in the later sections.

53.2 Materials

Many conductive polymers have been synthesised to provide certain electronic features (e.g. band gap, electron affinity). The monomer repeat units are often based on five- or six-membered (benzene) carbon ring systems, including polypyrrole, polythiophene (and various other polythiophene derivatives), polyphenylenevinylene and polyaniline [53.22]. The chemical structure of some of these materials is shown in Fig. 53.5. Such polymers generally show lower electrical conductivity than polyacetylene, however they can have the advantage of high stability and processability.

Conductive polymers represent only one category of organic electrical conductors. Another important class are the charge-transfer compounds [53.23, 24]. These are formed from a variety of molecules, primarily aromatic compounds (i.e. based on benzene) which can behave as electron donors (d) and electron acceptors (a). Complete transfer of an electron from a donor to an acceptor molecule results in a system that is electrically insulating (e.g. the transfer of a valence electron in a Na

atom to a Cl atom, forming the compound NaCl). However, if the ratio of the number of donor molecules to the number of acceptor molecules differs from 1 : 1, e.g. the stoichiometry is 1 : 2 or 2 : 3, or if there is incomplete transfer of an electron from a donor to an acceptor (say,

Fig. 53.5a–d Chemical structures of conductive polymers: (a) polypyrrole, (b) polyparaphenylene, (c) polyphenylenevinylene, and (d) polythiophene

Fig. 53.6 (a) Chemical structures of the charge-transfer compounds tetrathiafulvalene (TTF) and tetracyanoquinodimethane (TCNQ). (b) Oxidation and reduction of TCNQ

six electrons in every ten are transferred), then partially filled electron energy bands can be formed and electron conduction is possible.

Charge-transfer interactions are strongest between donor molecules of low ionisation potential and acceptor molecules of high electron affinity, provided that the donor and acceptor molecules have similar symmetry and are able to approach closely [53.24]. Well-known donor and acceptor molecules are tetrathiafulvalene (TTF) and tetracyanoquinodimethane (TCNQ), Fig. 53.6a. The latter compound is a very strong acceptor forming first the radical anion and then the dianion, Fig. 53.6b. The stability of the semireduced radical ion, $\text{TCNQ}^{\cdot-}$, with respect to the neutral molecule mainly arises from the change from the relatively unstable quinoid structure to the aromatic one, allowing extensive delocalisation of the π electrons over the carbon skeleton. As a consequence, TCNQ not only forms typical charge-transfer complexes but is also able to form true radical-ion salts, incurring complete one-electron transfer. Thus, on addition of lithium iodide to a solution of TCNQ, the simple lithium TCNQ salt is formed:

Following removal of the free iodine precipitate, the TCNQ salt may be crystallised. The crystals show an electronic conductivity of about 10^{-5} S/cm.

A 1 : 1 TCNQ : TTF salt exhibits a high room-temperature conductivity (5×10^2 S/cm) and metallic behaviour is observed as the temperature is reduced to 54 K. The molecules in such compounds are arranged in segregated stacks, in which the donors and accep-

Fig. 53.7a–c Chemical structure of C₆₀ (top) and three classes of single-wall carbon nanotube (SWNT) (a) (10,10) armchair SWNT, (b) (12,7) chiral SWNT and (c) (15,0) zigzag SWNT

tors form separate donor stacks (ddddd...) and acceptor stacks (aaaaa...). The molecules are stacked in such a way that the π bonds on successive molecules can overlap to form bands. This overlap is different from the p-orbital overlap forming the π bands in conjugated polymers. The crystalline packing in these, and other, charge-transfer compounds generally leads to carrier mobility values that are higher than for semiconductive polymers.

Other electroactive compounds that may find application in molecular electronics are based on forms of pure carbon. Graphite consists of vast carbon sheets stacked one on top of another like a sheaf of papers. In pure graphite, these layers are about 0.335 nm apart, but they can be separated further by intercalating various molecules. The bonding between the carbon atoms in the planes is mainly sp^2 hybridisations consisting of a network of single and double bonds. Weak interactions between the delocalised electron orbitals hold adjacent sheets together. The delocalised electron system in the planes results in semiconductive electrical behaviour.

Under certain conditions, carbon forms regular clusters of 60, 70, 84 etc. atoms [53.25, 26]. A C₆₀ cluster,

shown in Fig. 53.7, is composed of 20 hexagons and 12 pentagons and resembles a football. The diameter of the ball is about 1 nm. As with graphite, each carbon atom in C_{60} is bonded to three other carbon atoms. Thus C_{60} can be considered as a rolled up layer of a single graphite sheet. The term buckminsterfullerene was given originally to the C_{60} molecule because of the resemblance to the geodesic domes designed and built by Richard Buckminster Fuller. However, this term (or fullerene or buckyball) is used quite generally to describe C_{60} and related compounds. For example, a molecule with the formula C_{70} can be formed by inserting an extra ring of hexagons around the equator of the sphere, producing an elongated shell more like a rugby ball.

In addition to the spherical-shaped fullerenes, it is possible to synthesise tubular variations – carbon nanotubes [53.26, 27]. Such tubes are comprised of graphite-like sheets curled into a cylinder. Each tube may contain several cylinders nested inside each other. The tubes are capped at the end by cones or faceted hemispheres. Because of their very small diameters (down to around 0.7 nm), carbon nanotubes are prototype one-dimensional nanostructures. An important feature of a carbon nanotube is the orientation of the six-membered carbon ring in the honeycomb lattice relative to the axis of the nanotube. Three examples of single-wall carbon nanotubes (SWCNs) are shown in Fig. 53.7. The primary classification of a carbon nanotube is as either being chiral or achiral. An achiral nanotube is one whose mirror image has an identical structure to the original. There are only two cases of achiral nanotubes: armchair and zigzag (these names arise from the shape of the cross-sectional ring). Chiral nanotubes exhibit a spiral symmetry whose

mirror image cannot be superimposed on the original structure. Carbon nanotubes are characterised by the chiral index (n, m) where the integers n and m specify each carbon nanotube uniquely [53.27]. An armchair nanotube corresponds to the special case $n = m$, while for a zigzag nanotube $m = 0$. All other (n, m) indexes correspond to chiral nanotubes. The electronic structure of a SWCN is either metallic or semiconducting, depending on its diameter and chirality.

At low temperature, a single-wall carbon nanotube is a quantum wire in which the electrons in the wire move without being scattered. Resistance measurements for various nanotube samples show that there are metallic and semiconducting nanotubes [53.27]. Carbon nanotubes can also be doped either by electron donors or electron acceptors [53.28]. After reaction with the host materials, the dopants are intercalated in the intershell spaces of the multiwalled nanotubes, and, in the case of single-walled nanotubes, either in between the individual tubes or inside the tubes.

The above confirms carbon's uniqueness as an electronic material. It can be a good conductor in the form of graphite, an insulator in the form of diamond, or a flexible polymer (conductive or insulating) when reacted with hydrogen and other species. Carbon differs from other group IV elements, such as Si and Ge, which exhibit sp^3 hybridisation. Carbon does not have any inner atomic orbitals except for the spherical 1s orbital, and the absence of nearby inner orbitals facilitates hybridisations involving only the valence (outer) s and p orbitals. The fact that sp and sp^2 hybridisations do not readily occur in Si and Ge might be related to the absence of *organic materials* made from these elements.

53.3 Plastic Electronics

53.3.1 Diodes and Transistors

Since the discovery of semiconducting behaviour in organic materials, there has been a considerable research effort aimed at exploiting these properties in electronic and optoelectronic devices. The term *plastic electronics* refers to electronic devices incorporating polymeric organic compounds (although this term is often used more widely to include devices incorporating other semiconducting organic materials). Organic semiconductors can have significant advantages over their inorganic counterparts. For example, thin layers

of polymers can easily be made by low-cost methods such as spin coating. High-temperature deposition from vapour reactants is generally needed for inorganic semiconductors. Synthetic organic chemistry also offers the possibility of designing new materials with different band gaps. As noted in Sect. 53.1.3, the mobilities of the charge carriers in organic field-effect transistors are low. Nevertheless, the simple fabrication techniques for polymers have attracted several companies to work on polymer transistor applications such as data storage and thin-film device arrays to address liquid-crystal displays [53.20, 29–31].

Semiconducting organic compounds have been used in a similar fashion to inorganic semiconductors (e.g. Si, GaAs) in metal/semiconductor/metal structures. A diode, or rectifying device, can be made by sandwiching a semiconductor between metals of different work functions. In the ideal case, an n-type semiconductor should make an Ohmic contact to a low-work-function metal and a rectifying Schottky barrier to a high-work-function metal [53.32]. One example is that of a semiconductive organic film sandwiched between aluminium and indium-tin-oxide electrodes [53.33]. This device also exhibits photovoltaic behaviour.

Organic materials have been used as the semiconducting layer in field-effect transistor (FET) devices [53.20, 34–36]. These are three-terminal structures: a voltage applied to a metallic gate affects an electric current flowing between the source and drain electrodes. For transistor operation, charge must be injected easily from the source electrode into the organic semiconductor and the carrier mobility should be high enough to allow useful quantities of source–drain current to flow. The organic semiconductor and other materials with which it is in contact must also withstand the operating conditions without thermal, electrochemical or photochemical degradation. Two performance parameters to be optimised in organic field-effect transistors are the field-effect mobility and the on/off ratio [53.35].

The operating characteristics of organic transistors and integrated circuits have improved markedly over recent years. This has been brought about by both improvements in the material synthesis and in the thin-film processing techniques [53.37–45]. State-of-the-art organic FETs possess characteristics similar to those of devices prepared from hydrogenated amorphous silicon, with mobilities around $1 \text{ cm}^2/\text{Vs}$ and on/off ratios greater than 10^6 . A number of groups have also demonstrated transistor devices incorporating carbon nanotubes [53.46–48]. However, some key issues need to be addressed before nanotubes can be exploited fully in such applications. These include the reproducible fabrication of low-resistance electrical contacts and the accurate control of nanotube growth parameters [53.49]. The nanotube transistor devices realised experimentally have typical dimensions in the micron range. The real promise of carbon nanotube devices, however, lies in the possibility of nanoscale devices.

Thin-film transistors based on organic semiconductors are likely to form key components of plastic circuitry for use as display drivers in portable computers and pagers, and as memory elements in transaction cards and identification tags.

53.3.2 Organic Light-Emitting Structures

Reports of light emission from organic materials on the application of an electric field (electroluminescence) have been around for many years. However, there has been an upsurge in interest following the initial report of organic light-emitting devices (OLEDs) incorporating the conjugated polymer polyphenylenevinylene (PPV, Fig. 53.5) [53.50]. The simplest OLED is an electroluminescent compound sandwiched between metals of high and low work function, as depicted in Fig. 53.8. The anode electrode is normally indium tin oxide (ITO) as this material is semitransparent, allowing the light out of the device. On application of a voltage, electrons are injected from the low work function electrode into the lowest unoccupied molecular orbital (LUMO) level (conduction or π^* band in the case of an organic compound possessing a delocalised electron system) of the organic compound and holes from the high-work-function electrode into the highest occupied molecular orbital (HOMO) level (valence or π band in the case of an organic compound possessing a delocalised electron system). The recombination of these oppositely charged carriers then results in the emission of light. Work is focused on the use of low-molecular-weight organic molecules and polymers and there is considerable industrial interest in the application of such materials to various display technologies [53.51–54]. It is estimated that the global market for OLED displays will

Fig. 53.8 Schematic energy band structure of an organic light-emitting device (OLED). The recombination of electrons and holes results in the emission of light of frequency ν and energy $h\nu$

Fig. 53.9 External quantum efficiency versus current for OLEDs fabricated with MEH-PPV/DFD blended layers using blends with various concentrations (by weight) of DFD. (After *Ahn et al.* [53.56], with permission, © AIP)

increase from \$112 million in 2003 to almost \$2.3 billion by 2008 [53.55]. Organic light-emitting devices offer a number of advantages over liquid-crystal displays (LCDs) and the other technologies that currently dominate the flat-panel display market: OLEDs do not require backlighting and they can be made thinner and lighter. Furthermore, OLED displays provide higher contrast and truer colours, higher brightness, wider viewing angles, better temperature stability and faster response times than LCDs [53.54].

Many techniques have been used in attempts to optimise the performance of OLEDs. For example, a thin inorganic insulating layer such as LiF, or an organic monolayer may be inserted between the cathode and the emissive material [53.57, 58]. Electron- and hole-transporting layers can also be introduced between the cathode and the emitting layer and between the anode and the emitting layer, respectively, to improve and balance the injection of charge carriers [53.51]. As an alternative, OLEDs based on blended single layers of emissive and charge-transport materials may be fabricated [53.56, 59–61]. Such devices generally possess lower efficiencies than multilayer structures but they have the considerable advantage of ease of manufacture. Figure 53.9 shows how the external quantum efficiency of a blended layer OLED based on a polymer – poly[2,–(2-ethylhexyloxy)–5-methoxy–1,4-phenylenevinylene] (MEH-PPV) – and an electron-

Table 53.2 Performance of polymer-based organic light-emitting devices. (Data from Cambridge Display Technology [53.54])

Colour	Voltage (V)	Efficiency at 100 cd/m ² (lm/W)	Measured lifetime at room temperature at fixed luminance (h) at (cd/m ²)
Red	3.6	1.5	1790 at 2000
Green	2.6	9.4	2867 at 2000
Blue	5.5	3.9	1426 at 720

^a All data taken using common cathode and may include an interlayer

transport compound – 2,7-bis[2–(4-tert-butylphenyl)–1,3,5-oxadiazol-5-yl]–9,9-dihexylfluorene (DFD) – varies as the ratio MEH-PPV : DFD is changed in a spin-coated film [53.56]. The device efficiency increases with the amount of DFD so that the OLED fabricated with a 95% blend is about 100 times more efficient than that of pure MEH-PPV. For all the devices, the electroluminescence originates from the MEH-PPV material, indicating that the energy, or charge, transfer between the electron-transport compound and the polymer is very efficient.

When an electron and a hole recombine to form an excited molecular state in an organic material, the spins of the electrons in the excited and ground levels can either point in the same direction (triplet state) or in the opposite directions (singlet state). For quantum-mechanical reasons, 75% of recombination events are associated with triplet states which, in most cases, do not emit photons when they decay to the ground state. Hence, the production of emission from the triplet state of organic materials is a further means to improve the device efficiency [53.52, 62].

Table 53.2 shows some important parameters of polymer-based OLEDs with different colour outputs [53.54]. There is also a keen interest in developing white-light organic displays. For example, a large-area white-light-emitting OLED could provide a solid-state light source that might compete with conventional lighting technologies. Different methods of making an intrinsically white-emitting OLED by blending emissive species, either in single or multiple layers have been demonstrated [53.63–65]. Alternatively, a blue OLED can be used with one or more down-conversion layers [53.66].

53.3.3 Photovoltaic Devices

Concerns over global climate change, local air pollution and resource depletion are making photovoltaics (PVs) an increasingly attractive method of energy supply. The current technology is based on single-crystal silicon solar cells. These have developed since the 1940s and now possess conversion efficiencies of around 15% for commercial devices (although figures of around 25% are reported in the laboratory). However, the technology is more expensive than conventional power generation and there is much research on alternative materials. Photovoltaics using organic compounds, such as polymers or dyes, offer the possibility of large-scale manufacture at low temperature coupled with low cost. Until the end of the 20th century little progress had been made and energy conversion efficiencies of up to only about 1% were achieved. However, the availability of new conductive organic materials and different PV designs have significantly improved on this figure. To 2004, several laboratories have reported conversion efficiencies of 4–5%, with lifetimes of around 10⁴ hours [53.67].

An organic solar cell device is very similar in structure to the OLED described in the previous section. If the incoming photons have energy greater than the band gap of the polymer (or greater than the HOMO–LUMO separation in the case of organic molecular materials) then the light will be absorbed, creating electrons and holes. In an inorganic photovoltaic cell, these electrons and holes would be generated within, or close to, a depletion region in the semiconductor and they would be free to migrate to opposite electrodes, where they can do useful work in an external electrical load. However, in the organic material the electrons and holes are bound together in excitons. An immediate problem in organic PV cells is to split these excitons. This can be conveniently done at an interface, the simplest being the junction between the electrodes and the organic material. Under open-circuit conditions, holes are collected at the high-work-function electrode (e.g. ITO) and electrons at the low-work-function electrode (e.g. Al). The open-circuit output voltage of the PV device depends on the work-function difference between the electrodes. Improvements in the efficiency of the exciton-splitting process can be achieved using organic compounds incorporating electron-donating and electron-accepting species. By creating interfaces of differing electron affinities, it is possible to enhance the probability of electron transfer between the molecules.

An alternative approach to organic PVs exploits a dye-sensitised solar cell, or Grätzel cell [53.68]. Here,

the incoming photons are absorbed by molecules of a dye on a semiconductor surface with subsequent energy and electron transfer to the semiconductor. An electron is returned to the oxidised dye via an electrolyte. The efficiency of such devices can approach 10% [53.69].

53.3.4 Chemical Sensors

The development of effective devices for the identification and quantification of chemical and biochemical substances for process control and environmental monitoring is a growing need [53.70–72]. Many sensors do not possess the specifications to conform to existing or forthcoming legislation; some systems are too bulky/expensive for use in the field. Inorganic materials such as the oxides of tin and zinc have traditionally been favoured as the sensing element [53.73]. However, one disadvantage of sensors based on metallic oxides is that they usually have to be operated at elevated temperatures, limiting some applications. As an alternative, there has been considerable interest in trying to exploit the properties of organic materials. Many such substances, in particular phthalocyanine derivatives, are known to exhibit a high sensitivity to gases [53.74]. Lessons can also be taken from the biological world; one household carbon-monoxide detector is designed to simulate the reaction between CO and haemoglobin. A significant advantage of organic compounds is that their sensitivity and selectivity can be tailored to a particular application by modifications to their chemical structure. Moreover, thin-film technologies, such as self-assembly or layer-by-layer electrostatic deposition, enable ultrathin layers of organic materials to be engineered at the molecular level [53.75].

There are many physical principles upon which sensing systems might be based; changes in electrical resistance (chemiresistors), refractive index (fibre-optic sensors) and mass (quartz microbalance) have all been exploited in chemical sensing. The main challenges in the development of new sensors are in the production of cheap, reproducible and reliable devices with adequate sensitivities and selectivities.

A simple chemiresistor sensor exploits the resistance change of a thin layer of a gas-sensitive material. For example, the conductivity of phthalocyanine thin films can be changed in the presence of oxidising or reducing gases [53.76]. This effect is analogous to the doping of an inorganic semiconductor, such as silicon, with acceptor or donor impurities (Sect. 53.1.3). A problem associated with these chemiresistor devices is that the current outputs are low (typically picoamperes) requiring elaborate

detection electronics and careful shielding and guarding of components. This difficulty may be overcome by incorporating the organic sensing layer into a silicon field-effect transistor. A schematic diagram of such a structure is shown in Fig. 53.10 [53.77, 78]. Changes in the sheet resistance of the sensing layer are reflected in the variation in both the amplitude and phase of the transfer function of the device. These devices have been shown to respond well to low (vapour parts per million) concentrations of NO_2 [53.79]. It is also possible to use a chemically sensitive organic film as the semiconductive layer in a diode or a transistor. In these cases the device must be fabricated so that the gas can interact readily with the organic material.

While many sensing devices show adequate sensitivities, the selectivity can be poor. For example, a semiconductive polymer may show a similar change in electrical resistance to a range of oxidising (reducing) gases. To get around this difficulty, one approach that is being embraced enthusiastically by researchers is to use an array of sensing elements, rather than a single device. This is the method favoured by nature. The human olfactory system has many receptor cells (sensors), which are individually nonspecific; signals from these are fed to the brain via a network of primary and secondary neurons for processing. It is generally believed

Fig. 53.10 Structure of hybrid silicon/organic field-effect transistor for chemical sensing. (After Barker et al. [53.78])

that the selectivity of the olfactory system is a result of a high degree of parallel processing in the neural architecture. Artificial neural networks can emulate the connectivity of the olfactory neurons. The electronic nose is an attempt to mimic the human olfactory system and there are now several companies marketing such equipment [53.80]. Individual sensors can be based on polymer films. Each element is treated in a slightly different way during deposition so that it responds uniquely on exposure to a particular gas or vapour. The pattern of resistance changes in the sensor array can then be used to fingerprint the vapour.

53.4 Molecular-Scale Electronics

53.4.1 Moore's Laws

The second strand to molecular electronics (molecular-scale electronics) recognises the spectacular size reduction in the individual processing elements in integrated circuits over recent years. The first microprocessor chip manufactured in 1972 by Intel (8008) had a clock speed of 200 kHz and contained 3500 transistors. There are 55 million transistors on the Pentium® 4 chip (November, 2002), fabricated using 0.13- μm process technology, and operating at a clock speed of 3 GHz.

Moore's law (or Moore's first law) states that the functions per chip double every 1.5 years. This will probably describe developments over at least the next decade. The semiconductor industries have produced an international technology roadmap for the future of complementary metal oxide semiconductor (CMOS) technology [53.81]. Figure 53.11 shows the anticipated growth in the density of the transistors in both the microprocessor unit (MPU) and the dynamic random-access memory (DRAM) of a CMOS chip over the next decade.

Fig. 53.11 Predicted feature size in CMOS devices. (After [53.81])

Table 53.3 Information content for various applications. (After Tour [53.3])

Application	Typical information content (bytes)
Color photograph	10^5
Average book	10^6
Desktop computer	10^8
Genetic code	10^{10}
Human brain	10^{13}
Library of congress	10^{15}

The prediction is for a 30-nm minimum feature size (gate length) for the MPU and 10^{10} transistors per cm^2 in the case of the memory by the year 2012. These figures are regularly updated. This device density is remarkable and provides the means to store significant amounts of data, Table 53.3 [53.3]. However, molecular-scale electronics has the potential for further increases in device density. For example, using $\sim 1\text{--}3$ nm organic molecules as the processing elements, $10^{13}\text{--}10^{14}$ ‘devices’ could be fitted into 1 cm^2 [53.3].

There are, however, a number of technological problems issues that will need to be overcome for the predictions for the CMOS-based roadmap to be realised [53.82]. Not least, are the materials limitations of the silicon/silicon dioxide system. For example, charge leakage becomes a problem when the insulating silicon dioxide layers are thinned to a few nm. Heat dissipation is another key factor. A Pentium® 4 chip, with $10^7\text{--}10^8$ transistors operating at the current nanosecond rate can emit 50–60 W of heat. Financial issues are also problematic as ever more complex integrated circuits are produced. Intel’s Fab 22, a chip-fabrication facility (FAB) which opened in Chandler, Arizona in October 2001, cost \$2 billion to construct and equip. The cost of building a fab is projected to rise to \$15–30 billion by 2010 and could be as much as \$200 billion by 2015 [53.83]. This significant increase in cost (Moore’s second law) is due to the extremely sophisticated tools that will be needed to form the increasingly small features of the devices. Molecular-scale technology will, of course, also need to address such problems – plus many more.

53.4.2 Nanoscale Organic Films

Before organic molecules can be exploited in device architectures (i.e. those familiar from Si-based microelectronics) ways must be found to deposit them onto surfaces. Well-established methods of organic film de-

**Fig. 53.12** System for the deposition of Langmuir–Blodgett films

position include electrodeposition, thermal evaporation and spinning [53.84]. The Langmuir–Blodgett (LB) technique, self-assembly and layer-by-layer electrostatic deposition are further means for producing layers of organic materials. These allow ultrathin-film assemblies of organic molecules to be engineered at the molecular level and are of particular relevance to molecular-scale electronics [53.85, 86].

Langmuir–Blodgett films are prepared by first depositing a small quantity of an amphiphilic compound (i.e. one containing both polar and nonpolar groups) dissolved in a volatile solvent onto the surface of purified water [53.86, 87]. The classical materials are long-chain fatty acids, such as *n*-octadecanoic acid (stearic acid). When the solvent has evaporated, the organic molecules may be organised into a floating two-dimensional *crystal* by compression on the water surface. As the area available to the organic molecules is reduced, the floating film will undergo several phase transformations. These are, to a first approximation, analogous to three-dimensional gas, liquid and solid phases. The phase changes may readily be identified by monitoring the surface pressure as a function of the area occupied by the molecules in the film. This is the two-dimensional equivalent to the pressure-versus-volume isotherm for a gas. In the *gaseous* state the molecules are far enough apart on the water surface that they exert little force on one another. As the surface area of the monolayer is reduced, the hydrocarbon chains will begin to interact. The *liquid* state that is formed is generally called the expanded monolayer phase. The hydrocarbon chains of the molecules in such a film are in a random, rather than regular orienta-

tion, with their polar groups in contact with the subphase. As the molecular area is progressively reduced, condensed phases may appear. There may be more than one of these and the emergence of each condensed phase can be accompanied by constant-pressure regions of the isotherm, as observed in the cases of a gas condensing to a liquid and a liquid solidifying. In the condensed monolayer states, the molecules are closely packed and are oriented with their hydrocarbon chain pointing away from the water surface. The area per molecule in such a state will be similar to the cross-sectional area of the hydrocarbon chain, i. e. $\approx 0.19 \text{ nm}^2/\text{molecule}$.

If the surface pressure is held constant in one of the condensed phases, then the film may be transferred from the water surface onto a suitable solid substrate simply by raising and lowering the latter through the monolayer–air interface. Figure 53.12 shows a schematic diagram of the equipment required for LB film deposition. In this technique, introduced by Langmuir and Blodgett [53.86] the floating condensed monolayer is transferred, like a carpet, as the substrate is raised and/or lowered through the air/monolayer interface. A number of different LB deposition *modes* are possible. The most commonly encountered situation is Y-type deposition, which refers to monolayer transfer on both the upward and downward movements of the substrate. Instances in which the floating monolayer is only transferred to the substrate as it is being inserted into the subphase, or only as it is being removed, are also observed. These deposition modes are called X-type and Z-type deposition, respectively.

Self-assembly is a much simpler process than that of LB deposition. Monomolecular layers are formed by the immersion of an appropriate substrate into a solution of the organic material [53.85]. The best known examples of self-assembled systems are organosilicon on hydroxylated surfaces (SiO_2 , Al_2O_3 , glass etc.) and alkanethiols on gold, silver and copper. However, other combinations include: dialkyl sulphides on gold; dialkyl disulphides on gold; alcohols and amines on platinum; and carboxylic acids on aluminium oxide and silver. The self-assembly process is driven by the interactions between the head group of the self-assembling molecule and the substrate, resulting in a strong chemical bond between the head group and a specific surface site, e.g. a covalent Si–O bond for alkyltrichlorosilanes on hydroxylated surfaces.

The combination of the self-assembly process with molecular recognition offers a powerful route to the development of nanoscale systems that may have technological applications as chemical sensing or switching

Fig. 53.13 Deposition of layer-by-layer polyelectrolyte films by the sequential immersion of a solid substrate in solutions of the polyanions and polycations

devices. For instance, the complexation of a neutral or ionic guest at one site in a molecule may induce a change in the optical or redox properties of the system. Monolayers containing both an electroactive TTF unit and a metal-binding macrocycle assembled onto platinum have been shown to exhibit electrochemical recognition to Ag^+ ions [53.88].

The self-assembly process, as described above, is usually restricted to the deposition of a single molecular layer on a solid substrate. However, chemical means can be exploited to build up multilayer organic films. A method pioneered by Sagiv is based on the successive absorption and reaction of appropriate molecules [53.89, 90]. The head groups react with the substrate to give a permanent chemical attachment and each subsequent layer is chemically attached to the one before in a very similar way to that used in systems for supported synthesis of proteins.

Another technique for building up thin films of organic molecules is driven by the ionic attraction between opposite charges in two different polyelectrolytes, the so-called *layer-by-layer* assembly technique [53.91–93]. A solid substrate with a positively charged planar surface is immersed in a solution containing an anionic polyelectrolyte and a monolayer of polyanion is adsorbed, Fig. 53.13. Since the adsorption is carried out at relatively high concentrations of the polyelectrolyte, most of the ionic groups remain exposed to the interface with the solution and thus the surface charge is reversed. After rinsing in pure water, the substrate is immersed in a solution containing the cationic polyelectrolyte. Again, a monolayer is adsorbed but now the original surface charge is restored, resulting in the formation of a multilayer assembly of both polymers. It is possible to use a sensitive optical technique, such as surface plasmon resonance to monitor, in situ, the growth of such electrostatically assembled films [53.94]. The layer-by-layer method has been used to build up layers of conductive poly-

Fig. 53.14 Atomic force micrograph of a 12-layer, *n*-eicosanoic-acid Langmuir–Blodgett film deposited onto silicon. (After, in part, with permission from *Evanson et al.* [53.98]. © (1996) ACS)

mers, e.g. partially doped polyaniline and a polystyrene polyanion [53.95]. Biocompatible surfaces consisting of alternate layers of charged polysaccharides and oppositely charged synthetic polymers can also be deposited in this way [53.96]. A related, but alternative, approach uses layer-by-layer adsorption driven by hydrogen-bonding interactions [53.97].

The organisation of the organic molecules in multilayer assemblies may be investigated by a number of analytical techniques including X-ray and neutron reflection, electron diffraction and infrared spectroscopy [53.86]. Figure 53.14 shows an example of an atomic force micrograph of a 12-layer *n*-eicosanoic acid LB film deposited onto single-crystal silicon [53.98]. Lines of individual molecules are evident at the magnification shown. Figure 53.15 contrasts the molecular organisation expected in an LB multilayer with that in electrostatically deposited layer-by-layer films. For the latter case, the polyelectrolyte chains within each layer will become entangled, and may even penetrate into the layers above and below, leading to a less-ordered film than that produced by LB deposition.

53.4.3 Patterning Technologies

The problem of connecting together the individual processing elements in any future molecular computer is challenging. Each one of the 55 million transistors in the

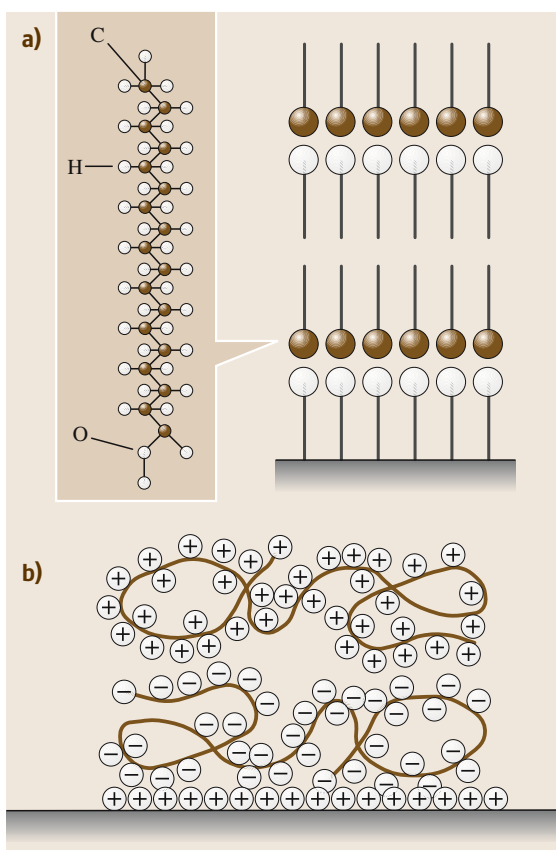

Fig. 53.15a,b Molecular organisation in (a) a Langmuir–Blodgett multilayer assembly and (b) a polyelectrolyte multilayer deposited by the electrostatic method

Pentium®4 chip is addressable and connected to a power supply. Organic molecules can be difficult to arrange on a surface or in a three-dimensional array such that each molecule is addressable. Planar inorganic materials are normally patterned using photolithography. Here, a surface is first covered with a light-sensitive photoresist, which is exposed to ultraviolet light through a contact mask. Either the exposed photoresist (positive resist) or the unexposed regions (negative resist) can then be developed to leave a positive or negative image of the mask on the surface. This approach is routinely used in the fabrication of devices based on inorganic semiconductors. However, difficulties can be encountered when used with organic films, as the photoresists themselves are based on organic compounds.

Brittain et al. [53.99] describe a series of *soft* lithographic methods that may be better suited to the patterning of organic layers. Pouring a liquid polymer,

Fig. 53.16 Dip-pen patterning showing the transfer of an *ink* onto *paper* using the tip of an atomic force microscope. (After Piner et al. [53.100])

such as polydimethylsiloxane (PDMS) onto a *master* made from silicon forms a pattern-transfer element. The polymer is allowed to cure to form an elastomer, which can then be removed from the master. This replica can subsequently be used as a stamp to transfer chemical ink, such as a solution of an alkanethiol, to a surface.

Scanning microscopy methods offer a powerful means of manipulating molecules. Careful control of an atomic force microscope (AFM) tip can allow patterns to be drawn in an organic film [53.101, 102]. Such techniques can also be used to reposition molecules, such as the fullerene C_{60} , on surfaces and to break up an individual molecule [53.103]. A further approach that has recently been developed is called dip-pen nanolithography (DPN) [53.100], Fig. 53.16. This is able to deliver organic molecules in a positive printing mode. An AFM tip is used to *write* alkanethiols on a gold thin film in a manner analogous to that of a fountain pen. Molecules flow from the AFM tip to a solid substrate (*paper*) via capillary transport, making DPN a potentially useful tool for assembling nanoscale devices. Recent developments of DPN have included an overwriting capability that allows one nanostructure to be generated and the areas surrounding that nanostructure to be filled with a second type of ink [53.104]. Perhaps the greatest limitation in using scanning probe methodologies for ultrahigh-resolution nanolithography over large areas derives from the serial nature of most techniques. However, an eight-pen nanoplotter capable of doing parallel lithography has been reported [53.105]. The DPN method has also been used to deposit magnetic nanostructures [53.106] and arrays of protein molecules [53.107].

The need to combine large-area coatings with device patterning has resulted in the development of direct-write fabrication methods, such as ink-jet printing [53.108–110]. Although ink-jet printhead droplet

ejection can be achieved with thermal (bubble-jet) and piezoelectric modes of operation, the majority of published literature on ink-jet printing as a tool for manufacturing organic devices has been the result of using piezoelectric-actuated printers. Piezoelectric printhead technology is favoured primarily because it applies no thermal load to the organic *inks* and is compatible with the printing of digital images. The combination of solution-processable emissive polymers with ink-jet printing offers some promise in the development of low-cost high-resolution displays [53.111]. The technique has also been applied to the manufacture of all-polymer transistor circuits [53.112, 113].

53.4.4 Molecular Device Architectures

The *bottom-up* approach to molecular electronics offers many intriguing prospects for manipulating materials on the nanometre scale, thereby providing opportunities to build up novel architectures with predetermined and unique physical and/or chemical properties. Two relatively simple examples of organic superlattice structures are the incorporation of an electric polarisation into a multilayer array to form thin films exhibiting pyroelectric behaviour [53.114] and the use of non-centrosymmetric layers for second-order nonlinear optical response, e.g. second-harmonic generation [53.115]. In both instances, the multilayer thin films can be built up using the **LB** approach.

To realise functional nanoelectronic circuits, a number of workers have investigated the electrical characteristics of structures in which organic molecules are sandwiched between two metallic electrodes. Of particular interest is the possibility of observing molecular rectification using monolayer or multilayer films. This follows the prediction [53.116] that an asymmetric organic molecule containing a donor and an acceptor group separated by a short σ -bonded bridge, allowing quantum-mechanical tunnelling, should exhibit diode characteristics. There have been many attempts to demonstrate this effect in the laboratory, particularly in organic thin films [53.117–119]. Asymmetric current-versus-voltage behaviour has certainly been recorded for many metal/insulator/metal structures, although these results are often open to several interpretations as a result of the asymmetry of the electrode configuration.

In other cases *switching* behaviour has been reported [53.3–8, 12, 13, 119]. As with the work on molecular rectification, the origin of the switching is not always clear. For example, is this a property of the organic molecules, the metallic electrode or of the

Fig. 53.17 (a) Bistable rotaxane. (b) Schematic diagram of cross-wire structure for switching studies. (After Chen et al. [53.5])

presence of any interfacial (e.g. oxide) layer (or a combination of these)? Bistable rotaxane molecules have been used as the basis of some of these studies, an example is shown in Fig. 53.17a. This molecule is amphiphilic and the ring component can move between the polar and nonpolar regions of the main part of the molecule. The molecules can be assembled on an electrode using the LB approach and a top electrode then deposited to form the crossbar structure shown in Fig. 53.17b [53.5–7]. Alternatively, the molecules can be solution-cast between Pt source and drain electrodes (with gaps of 1–2 nm) in transistor structures [53.9]. In some of the experiments,

the absence of switching using *control* compounds suggests that the rotaxane molecule itself is responsible for the bistability [53.7]. Such results augur well for the development of molecular-scale logic circuitry.

Nanoscale organic devices can also exploit charge storage on nanoparticles or at interfaces. One important metal oxide semiconductor (MOS) device is the flash memory [53.120]. This is similar in structure to a MOS field-effect transistor (MOSFET), except that it has two gate electrodes, one on top of the other. The top electrode forms the control gate, below which a *floating gate* is capacitively coupled to the

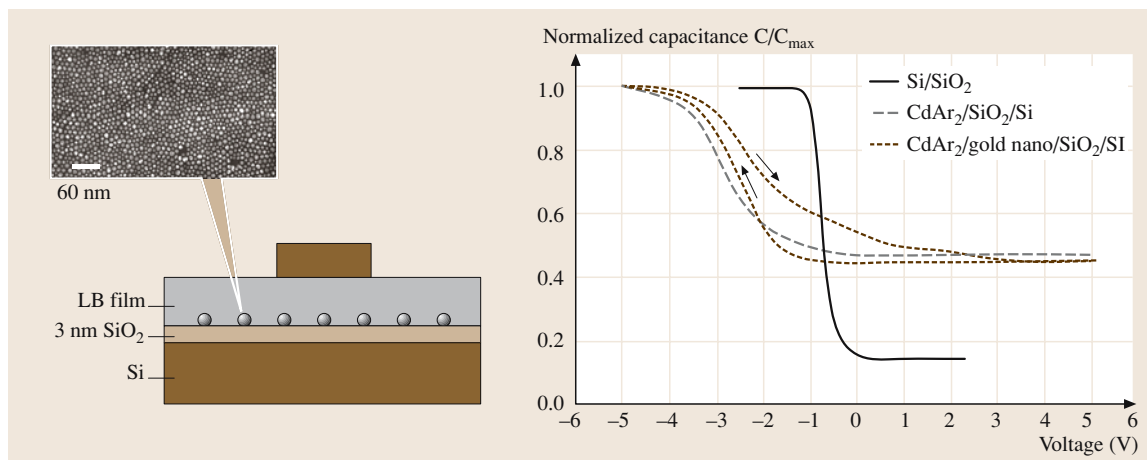

Fig. 53.18 Left: metal–insulator–semiconductor (MIS) structure incorporating gold nanoparticles; a transmission electron micrograph of the nanoparticles is shown. Right: normalised capacitance versus voltage characteristics for different MIS devices. (After Paul et al. [53.10], © (2003) ACS)

Fig. 53.19 (a) Molecular memory holding N bits (top) compared to a conventional silicon memory holding 1 bit (bottom). (b) Electron energy versus perpendicular distance for molecular memory with no applied electric field. (After Burrows et al. [53.123], with permission, © Elsevier [123])

control gate and the underlying silicon. The memory cell operation involves putting charge on the floating gate or removing it, corresponding to two logic levels. Nanoflash devices utilise single or multiple nanoparticles as the charge-storage elements. These are usually embedded in the gate oxide of a field-effect transistor and located in close proximity (2–3 nm) to the transistor channel [53.121]. Figure 53.18 shows the characteristics of a memory device incorporating metallic nanoparticles deposited by the LB technique [53.10]. The device structure is shown schematically in the figure. The gold nanoparticles (Q-Au) were of nominal

diameter 10 nm and passivated with an organic capping layer. Cadmium arachidate (CdAr_2) LB layers were used to provide an insulating gate layer. Figure 53.18 also shows the normalised capacitance versus voltage ($C-V$) data, measured at 1 MHz and at a voltage scan rate of 40 mV/s for three different device structures: Al/SiO₂/p-Si; Al/20 LB layers CdAr₂/SiO₂/p-Si; and Al/20 LB layers CdAr₂/one LB layer Q-Au/p-Si. The $C-V$ curve for the reference Al/SiO₂/Si sample reveals the usual accumulation/depletion/inversion characteristics associated with metal–insulator–semiconductor (MIS) structures, with a flat-band voltage of approximately -1 V. Negligible hysteresis was evident on reversing the voltage scan. The data for the Si/SiO₂/CdAr₂ structure also show clear accumulation, depletion and inversion regions, again with no hysteresis on reversing the direction of the voltage scan. The most significant difference in the structures with and without the Q-Au nanoparticles is the relatively large hysteresis in the MIS structure containing the Q-Au layer. This was thought to be indicative of charge storage in the gold nanoparticles [53.10]. In a somewhat different approach, the same group has used a self-assembly technique to chemically attach gold nanoparticles to a SiO₂ surface [53.122]. When incorporated into a transistor structure, the resulting device was shown to behave as a nonvolatile electrically erasable programmable read-only memory.

Molecular-scale electronics may also offer increased device densities by fabricating three-dimensional architectures. In 1989, the principle of a three-dimensional memory based on LB films was described [53.123]. The device requires a molecule with a central conjugated region of high electron affinity (for an n-type material, the electron affinity is the energy difference between the bottom of the conduction band and the vacuum level) surrounded by aliphatic substituents of low electron affinity. A multilayer structure, as shown in Fig. 53.19, could be used to store one N -bit word, the presence or absence of charge on the n -th layer representing a 0 or 1 of the n -th bit. The LB film could be assembled on the gate of an FET and, on application of an electric field, transport of bits across the layers may be detected as induced charge on the gate.

53.5 DNA Electronics

The study of the electronic behaviour of organic compounds has led some scientists to work on the electrical properties of biological materials. Deoxyribonucleic

acid (DNA) is arguably the most significant molecule in nature. It may also be an important material for molecular electronics applications. Reports into the

Fig. 53.20 DNA double helix showing the position of the four bases: guanine (G), cytosine (C), adenine (A) and thymine (T)

electronic properties of DNA have already generated controversy in the literature [53.16, 124–128]. According to some, DNA is a molecular wire of very small resistance. Others, however, find that DNA behaves as an insulator. These seemingly contradictory findings can probably be explained by the different DNA sequences and experimental conditions used to monitor the conductivity [53.16].

The DNA strand in the double-helix arrangement consists of a long polymer backbone consisting of repeating sugar molecules and phosphate groups, Fig. 53.20. Each sugar group is attached to one of four bases, guanine (G), cytosine (C), adenine (A) and thymine (T). The chemical bonding is such that an A base only ever pairs with a T base, while a G always pairs with a C. Some of the electron orbitals belonging to the bases overlap quite well with each other along the long axis of the DNA. This provides a path for elec-

tron transfer along the molecule, in a similar fashion to the one-dimensional conduction seen in conjugated polymers, Sect. 53.1.2.

Theoretical and experimental work now suggests that a hole (i. e. a positive charge) is more stable on a G–C base pair than on an A–T base pair [53.16]. The energy difference between these two pairs is substantially larger than the thermal energy of the charge carrier. Under these conditions, a hole will localise on a particular G–C base pair. Because the A–T base pairs have a higher energy, they act as a barrier to hole transfer. However, if the distance between two G–C base pairs is small enough, the hole can tunnel quantum-mechanically from one pair to the next. In this way, charge carriers are able to shuttle along a single DNA molecule over a distance of a few nanometres.

DNA chips exploit the fact that short strands of DNA will bind to other segments of DNA that have complementary sequences, and can therefore be used to probe whether certain genetic codes are present in a given specimen of DNA. Microfabricated chips with many parallel DNA probes are becoming widespread in analytical and medical applications. Currently, the chips are read out optically, but further miniaturisation might require new read-out schemes, possibly involving the electron-transfer properties of DNA.

Computations by chemical or biological reactions overcome the problem of parallelism and interconnections in a classical system. If a string of DNA can be put together in the right sequence, it can be used to solve combinatorial problems. The calculations are performed in test tubes filled with strands of DNA. Gene sequencing is used to obtain the result. For example, *Adleman* [53.129] calculated the *travelling-salesman problem* to demonstrate the capabilities of DNA computing. DNA computing on parallel problems potentially provides 10^{14} millions of instructions per second (MIPS) and uses less energy and space than conventional supercomputers. While CMOS supercomputers operate 10^9 operations per Joule, a DNA computer could perform about 10^{19} operations per Joule. Data could potentially be stored on DNA in a density of approximately 1 bit per nm^3 while existing storage media such as DRAMs require 10^{12} nm^3 to store 1 bit.

53.6 Conclusions

Organic compounds possess a wide range of fascinating physical and chemical properties that make them attractive candidates for exploitation in electronic and

optoelectronic devices. It is not, however, anticipated that these materials will displace silicon in the foreseeable future as the dominant material for fast signal

processing. It is much more likely that organic materials will find use in other niche areas of electronics, where silicon and other inorganic semiconductors cannot compete. Examples already exist, such as liquid-crystal displays and certain chemical sensors. Organic light-emitting structures are likely to make a major impact in the marketplace over the next ten years.

Over the first decades of the 21st century, classical CMOS technology will come up against a number of technological barriers. The bottom-up approach to molecular electronics provides an alternative and attrac-

tive way forward and, as such, it is currently an area of exciting interdisciplinary activity. However, the challenges in fabricating molecular switches and connecting them together are formidable. Living systems use a different approach; these assemble themselves naturally from molecules and are extremely energetically efficient when compared with man-made computational devices. More radical approaches to materials fabrication and device design, exploiting self-organisation, may be needed to realise fully the potential offered by molecular-scale electronics.

54. Organic Materials for Chemical Sensing

Organic materials for chemical sensing are broadly classified into three categories: (i) macrocyclic compounds, (ii) conducting polymers and (iii) cavitand molecules. A short review of current progress in semiconductor oxide sensing materials is given, pointing out their strengths and limitations. Principal wet techniques for depositing organic thin films are described and electrical, optical and structural properties of all three types of organic materials are analysed in relation to their importance in chemical sensing. Examples of recent advances in chemical sensing of different analytes and pollutants are presented.

The development of a new generation of sensors involves the study of fine-tuned sensor-active materials and transducers [54.1, 2]. Metal oxides, polymer/polymer composites, and dyes are being regarded as key sensing materials. This chapter is organised into eight sections. The next section presents a summary of the needs for chemical sensing of different pollutants. The second section provides a brief description of different semiconducting oxide materials and their applications in sensor technology. Organised ultrathin organic films of molecular and polymeric semiconductors are currently the focus of considerable research with an emphasis on a molecular understanding of the sensing mechanisms. The low cost of fabrication, large-area processability, and widely diverse and tailorable physical, electronic, and optical properties have stimulated interest in their practical exploitation. Phthalocyanine and the related macrocyclic compounds have been extensively investigated for chemical sensing primarily because the desired functionality of phthalocyanine molecules can be achieved by changing the central metal atom or introducing substituents in their π -electron aromatic ring [54.3]. The third section is devoted to thin-film formulation of these

interesting compounds and their structural, electrical and optical properties relevant to sensing different types of pollutants. Important transduction methods and their applications in the development of practical sensors are presented in the fourth section, with an emphasis on the interaction at the interface of analyte/film of macrocyclic compounds. The ability of conducting polymers to change their physical properties during reaction with various redox agents makes them very useful for the development of gas sensors. The most common are polyaniline (PAni) and polypyrrole (PPY). It has been shown that the resistivity of polypyrrole increases in the presence of a reducing gas such as ammonia, but decreases in the presence of an oxidising gas such as nitrogen dioxide. The gases cause a change in the near-surface charge-carrier density by reacting with surface-adsorbed oxygen ions [54.4]. Sensing properties of polymers and their importance in the development of intelligent sensors are described in Sect. 54.5. A class of supramolecules, called cavitands, that exhibit discotic phases depending on the structure, are shown to have potential for sensing applications [54.5]. Section 54.6 deals with the applications of thin films of these

molecules such as calixresorcinarene for recognition of organic vapours. The chapter concludes by highlighting

the trends of future development of sensor materials and technology in Sect. 54.7.

54.1 Analyte Requirements

The detection of pollutant gases and volatile organic compounds (VOC) whether in gaseous phase or dissolved in water is of great environmental importance due to the extreme hazards posed by their presence in small amounts in the ambient. Nitrogen dioxide (NO₂), ozone (O₃), sulphur dioxide (SO₂), particulate matter (PM), carbon monoxide (CO), and lead (Pb) are six principal pollutants of major concern for maintaining the quality of air in urban areas (Table 54.1). Some of these pollutants, like CO, Pb, NO₂, PM and SO₂, are emitted directly from a variety of sources including industrial production growth and increased traffic congestion. Ozone is generally formed when emissions of NO₂, SO₂, ammonia (NH₃), VOCs, and other gases react in the atmosphere. The presence of ozone in high concentration is also possible in offices where laser printers and photocopiers are heavily used. On the other hand, water is commonly treated with O₃ to destroy microbial contaminants such as *Escherichia coli* and *salmonella* [54.6, 7] and there is a need for accurate calibration of ozone content. Due to its ability in absorbing ultraviolet (UV) radiation from sunlight, stratospheric ozone filters out damaging ultraviolet radiation from the sun. Monitoring of ozone in the stratosphere has thus become a global issue as it forms a protective shield for all forms of life on Earth.

Stringent domestic and international standard for emission control requires the monitoring of threshold

limit value of these pollutants in order to protect primarily against adverse public health hazards. For example VOCs and nitric oxide (NO_x) resulting from combustion processes cause respiratory problems. Benzene itself is regarded as a human carcinogen and vehicle exhaust is primarily composed of these toxic gases. Spillage in fuel stations also contribute to the emission of excessive amounts of aromatic hydrocarbons in the atmosphere. VOCs also bind with ground-level ozone and form a photochemical smog, causing breathing difficulty for asthma sufferers. The secondary requirement of pollution monitoring is to reduce disastrous effects on the preservation of ecosystems, plants and animals. Safeguard is also to be taken against the decreased visibility due to the presence of PM and damage to crops, vegetation, and buildings due to atmospheric pollution. The SO₂ content is known to attack the indoors and outdoors of buildings, and in particular the surface of historical glasses. A wide variety of preventive conservation tools and routines have been sought to protect historical and cultural objects against deterioration and degradation [54.8, 9].

The activities of chemical sensing are not solely limited to environmental control. Hydrogen (H₂) fuel cells are clean, quiet, more efficient generators of electricity than any other known technology. Hydrogen is also an important raw material for the aerospace, chemical and semiconductor industries. As hydrogen is explosive above the lower explosive limit (LEL), H₂ sensors have

Table 54.1 Air quality standards for the UK, USA and World Health Organisation (WHO)

Pollutant	UK		WHO		USA	
	Concentration	Standard measured	Concentration	Standard measured	Concentration	Standard measured
Benzene	5 ppb	Annual mean	Data not available			
1,3-butadiene	1 ppb	Annual mean	Data not available			
Carbon monoxide (CO)	8.6 ppm	8 h mean	8.6 ppm	8 h mean	9 ppm	8 h mean
Lead (Pb)	0.25 µg/m ³	Annual mean	0.5 µg/m ³	Annual mean	1.5 µg/m ³	Quarterly mean
Nitrogen dioxide (NO ₂)	21 ppb	Annual mean	105 ppb	1 h mean	0.05 ppm	Annual mean
Ozone (O ₃)	50 ppb	8 h mean	60 ppb	8 h mean	0.08 ppm	8 h mean
Particles (PM ₁₀)	50 µg/m ³	24 h mean	70 µg/m ³	24 h mean	50 µg/m ³	Annual mean
Sulphur dioxide (SO ₂)	100 ppb	15 min mean	188 ppb	10 min mean	0.14 ppm	24 h mean

now become important safety devices in all these applications. The oxygen sensor which detects the air–fuel mixture of a gasoline engine by measuring the amount of oxygen in the exhaust gas is an essential component of the car engine management system. The development of reliable oxygen sensors for medical application has received considerable research attention in recent years [54.10–12]. Drinking, industrial and swimming-pool water must be disinfected with suitable oxidising agents such as chlorine or chlorine compounds. The dosing of the appropriate oxidising agents must be carefully controlled to suit the application as a higher concentration can result in corrosion effects, impairment of taste or skin irritation. The ability of detection of chlorine in sub-ppm level is therefore essential [54.13]. Ammonia is increasingly used as a refrigerant alternative to ozone-depleting chlorofluorocarbon (CFC). Large quantities of ammonia can also be found in fertiliser factories, resin production plants using urea, explosives munitions plants, semiconductor industries and water utility facilities. The presence of ammonia can cause inhalation problem at a very low concentration (0.6–53 ppm). Airborne ammonia gas dissolves in moisture on the skin, forming corrosive ammonium hydroxide. The exposure of ammonia at 10 000 ppm is mildly irritating to moist skin but the effects become more pronounced with the increasing concentration, producing chemical burns with blistering at 30 000 ppm. Its solubility in water can cause it to cauterise respiratory tracts, resulting in deaths at concentrations of 5000 ppm. Research into the development of reliable ammonia sensors with

a fast response to a wide range of concentrations is intensive [54.14–16].

It is obvious from the brief survey above that growing demand exists for the fabrication of low-cost, low-power, robust and portable chemical sensors for a variety of pollutants, contaminants and analytes, showing improved sensitivity and selectivity for industrial, healthcare and environmental control. Analytical chemical tools provide advanced and reliable methods for detection of different analytes but those methods are in many cases prohibitively expensive, unsuited for large-scale field measurements or mobile monitoring. For instance, there is currently a good market for detection systems for ozone at low concentration (ppb level) to replace more expensive techniques such as UV absorption measurements [54.17]. Existing devices for the detection of ozone are now mostly based on electrochemical measurements [54.18], or on solid-state semiconductor devices [54.19]. Similarly, the detection of organic vapours involves extracting air samples and subsequently analysing them using standard laboratory techniques such as gas chromatography [54.20], mass spectroscopy and Fourier-transform infrared (FTIR) spectroscopy [54.21, 22]. The major disadvantages associated with these techniques are their complexity, the capital cost of the instruments used and the requirement for trained human resources for operation and the interpretation of data. Apart from environmental applications, the development of detection instrumentation of these species is also important for both human health monitoring [54.23, 24] and for odour detection [54.25].

54.2 Brief Review of Inorganic Materials

Solid-state semiconductor gas sensors are usually made of tin oxide (SnO_2) in the form of thick films, porous pellets or thin-film coatings to monitor the presence of various gases [54.26]. These sensors are being used in the intelligent automatic control of a large number of processes, ranging from microwave cooking to the efficient combustion of motor engines. SnO_2 sensors operate at high temperatures of 300–400 °C. Gases are adsorbed onto the surface in the presence of air and the semiconductivity of the metal oxide changes due to the formation of a surface depletion layer. The thickness of this layer can be expressed in terms of the Debye length $L_D = \sqrt{\epsilon_0 \epsilon k_B T / (q^2 n_0)}$, where ϵ_0 is the permittivity of free space, ϵ is the dielectric constant of the semiconducting material, n_0 is the total carrier concentration, q is the electronic charge, k_B is the Boltzmann constant,

and T is the absolute temperature [54.27]. The sensitivity of the sensor is generally defined as the ratio of the change in the conductance after the treatment to the conductance of the sensor in air and can simply written as $\Delta n L_D / n_0$, where Δn is the change in carrier concentration due to the analyte exposure. It is therefore possible to optimise the sensitivity by reducing grain size, lowering the carrier concentration and increasing the Debye length. The maximum sensitivity is assumed to have been achieved when the Debye length is about half the particle size.

Figure 54.1 shows a photograph of a comb-like interdigitated electrode (IDE) system used for most conductivity measurements. The original idea was developed by Taguchi [54.28] and the sample resistance in this configuration is smaller than that obtained from

Fig. 54.1 Interdigitated electrode (IDE) system for an SnO₂ sensor

the four-contact geometry. The output signal is normally logarithmic to gas concentration. The conductivity change of SnO₂ thick-film sensors was monitored on exposure to compounds forming in smouldering and combustion processes of natural materials, e.g. paper and wood. A strong response was observed for compounds with hydroxyl groups and the highest response was obtained for phenolic structures such as methoxyphenols and benzenediols [54.29]. The response of a SnO₂ sensor element operating at 270 °C produced no sensor response to toluene, furfural and acetone [54.30]. The impedance output from the SnO₂ sensor array was measured at 300 °C in terms of conductance changes and peak frequency changes. These changes were more the more sensitive to oxygenated VOCs than other VOCs. The sensors sensitivity could also be enhanced by Pd- and Pt-doped sensors [54.31].

Considerable development work is being carried out to integrate the semiconductor sensing membrane with the interrogation and control circuitry on a silicon chip using conventional silicon technology. Using an industrial 0.8-μm complementary metal-oxide-semiconductor (CMOS) process with subsequent micromachining steps, a CO gas-sensor chip was fully integrated with advanced analogue and digital circuitry on a chip for temperature control in the range 170–300 °C with an error of ±2 °C. The whole device was encapsulated using standard microelectronic packaging methods. It was reported that the integrated sensor was capable of measuring CO at the concentration of 5 ppm with a resolution of ±0.1 ppm [54.32].

Solid-state sensor technology relies on the preparation of semiconductor films. SnO₂ sensors suffer from a lack of selectivity and drift. The high temperature re-

quired for the surface reactions encourages the growth of grains by coalescence, giving rise to unstable materials. Recent progress in the synthesis of nanomaterials has been employed to overcome some of these problems. Oxide powders were thermally evaporated under controlled conditions without the presence of a catalyst to deposit single-crystalline SnO₂ nanobelts on a platinum IDE structure on an alumina substrate. The surface-to-volume ratio was very high but the size was large enough to contain the depletion layer within the belt. SnO₂ nanobelts were sensitive to CO, NO₂ and ethanol and therefore suitable for applications in breath analysis and food control [54.33].

Advanced methods of information technology are increasingly being used to address the issues regarding selectivity and specificity. A sensor array of two commercial metal-oxide gas sensors was developed to discriminate six organic solvents over a wide concentration range of 2–200 ppm in air. The baseline drift was considerably reduced over a test period of several months by temperature cycling. Further reduction in drift was achieved by suppressing the influence of humidity via additional signal preprocessing. Relatively low computing power was required for the hierarchical pattern classification to evaluate shape features generated from the sensor response curve during temperature cycling. The technique was found to be adaptable to different operating environments, for example, to suppress false alarms from interfering gases [54.34].

Apart from SnO₂, titania (TiO₂), ferric oxide (Fe₂O₃), titania doped chromium oxide (Cr_{1.8}Ti_{0.2}O₃), molybdenum trioxide (MoO₃), tungsten oxide (WO₃), indium oxide (In₂O₃) and perovskite-type thick films (LaFeO₃) were studied for sensing a host of analytes such as H₂, CO, NO₂, H₂S, NH₃ and CH₄ in the ppb range. The characteristics of titanium dioxide nanotube hydrogen sensors were found to be completely reversible, highly selective and free from hysteresis. The sensors showed response times of approximately 150 s at a nominal operating temperature of 180 °C. The sensitivity of the nanotubes was believed to be due to chemisorption of hydrogen onto the titania surface as electron donors. Increased operating temperature improved the sensitivity significantly but reduced the response time. Samples with smaller pore diameter (46 nm) were more sensitive to hydrogen than those with larger pore diameter (76 nm). The sensor showed response to high concentrations of oxygen but the response time was long and the recovery was not complete [54.35]. Ion-beam-deposited thin films of MoO₃ on alumina substrates with gold IDEs showed selective

response to NH_3 at 450°C . Similarly prepared WO_3 thin-film samples were highly sensitive to NO_2 . Both films exhibited orthorhombic structure but the poly-

morphic dissimilarities between two types of materials were responsible for the difference in their sensing behaviour [54.36].

54.3 Macrocylic Compounds for Sensing

Phthalocyanine (**Pc**) molecules belong to a class of macrocyclic compounds. Because of their 18 π -electron aromatic macrocyclic structure these molecules exhibit important optoelectronic, photophysical, conducting and photoconducting properties [54.37]. As shown in Fig. 54.2, the **Pc** structure is closely related to the naturally occurring porphyrins, which form a core skeleton in the haemoglobin and chlorophyll. Organic molecular nanostructures have huge potential but suffer from unstable device characteristics, low resistance to adverse environments (e.g., temperature, humidity, oxygen, etc.) and lack of reproducibility of material composition, purity, and fabrication conditions. **Pcs** are, however, tinctorially strong, chemically and thermally stable. The materials are abundantly available in a highly purified form.

54.3.1 Preparation of Sensing Membranes

Sensing is essentially an interaction mechanism of a solid surface and analytes and the molecules are organised in ultrathin films, offering a large surface-to-volume ratio to improve the probability of these reactions taking place. A variety of methods such as direct-current **DC** and radio-frequency **RF** sputtering [54.38], thermal evaporation [54.39], Langmuir–Blodgett (**LB**) [54.40], spin coating [54.41] and self-assembly (**SA**) [54.42] are employed to produce organised thin organic films.

Fig. 54.2a,b Chemical structure of: (a) a metal-free phthalocyanine and (b) porphyrin molecule

Fig. 54.3 Typical UV–visible spectra for thin films of metal-free phthalocyanine molecules in: (A) chloroform and (B) an **LB** film

The substrates play a key role in determining the film quality and the structure. It is found that the island density and coverage ratio of copper tetra-tert-butyl phthalocyanine (**CuTTBPc**) on hydrophilic glass surfaces were small during the early growth stage of vacuum deposition due to a small nucleation rate arising from

Fig. 54.4 Dark- (triangles) and photoconduction (circles) through spun **NiPc** films

the weak interaction of molecules. The film surface was also rough. The high nucleation rate of CuTTBPc on a silanized surface, on the contrary, produced a much smoother morphology consisting of densely distributed fine-grain clusters. The aggregation of the molecules took place in domains during the formation of the LB monolayer, separately distributed on the glass surface. These domains acted as active sites for the nucleation and growth of the later deposition process and high-density clusters were thus found in the early growth stage. X-ray diffraction (XRD) patterns demonstrated that the LB films grown on the glass substrate were more crystalline than those on other substrates [54.43].

The wet techniques, namely LB, spin coating and SA, are preferred to high-energy deposition because the deposition takes place at room temperature, reducing the possibilities of the chemical decomposition of the molecules caused by thermal damage. These deposition methods are considered below.

Langmuir–Blodgett (LB) technique

The LB method involves the transfer of individual Langmuir monolayers of amphiphilic molecules which self-assemble in an ultra-clean water subphase onto a suitably prepared solid substrate. An LB film, which may consist of a single or many layers, up to a depth of several visible-light wavelengths, are generally produced with fine control over the thickness and geometry to the precision at the molecular level. With the Y-

Fig. 54.5 Chemical structure of 1,4-bis(4-hydroxybutyl)-8,11,15,18,22,25-hexakisdecyl phthalocyaninato copper molecules

type construction, these LB films are essentially layered materials with alternating hydrophobic/hydrophilic regions. Non-centrosymmetric LB films can be obtained by X-type construction on immersion of the substrate from air into the water only, or Z-type deposition on withdrawal of the substrate from water to air [54.44].

Macrocylic molecules are not generally amphiphilic and are therefore not considered suitable for LB deposition. The synthesis of a series of specially designed Pc molecules for LB deposition has now been reported in the literature over the last two decades [54.45–47]. Figure 54.5 shows the chemical structure of asymmetrically substituted 1,4-bis(6-hydroxyhexyl)-8,11,15,18,22,25-hexa-octylphthalocyanine molecules belonging to this family of custom-designed molecules [54.48].

To start with LB deposition, a Langmuir monolayer is formed from a spreading solution of substituted Pc derivatives in an appropriate volatile solvent (such as chloroform) on the highly purified water subphase

Fig. 54.6a,b Deposition of Langmuir–Blodgett film: (a) surface pressure–area isotherms and (b) transfer of floating monolayer onto a suitable substrate floating monolayer

(Milli-Q water of resistivity of 0.18 M Ω m) contained in an LB trough made of a hydrophobic material (teflon). The solvent is allowed to evaporate fully and the molecules are then slowly compressed to the desired organisation by closing a servo-controlled teflon barrier straddling the air/water interface at a constant speed (say about 100 mm/min). As shown in Fig. 54.6, the phase changes of the molecules during the compression are monitored by recording the surface pressure–area isotherm. The pressure begins to rise rapidly as the solid phase is reached while the area per molecule remains approximately constant. The molecules are transferred from the water/air interface to the substrate by dipping the substrate in at a constant speed of about 10 mm/min when the surface pressure is in the range 20–40 mNm⁻¹. However a dipping rate as high as 1000 mm/min was used to produce LB films of 5,10,15,20-tetrakis(3,4-bis[2-ethylhexyloxyphenyl])-21H,23H-porphine (EHO) molecules. Atomic force microscopy (AFM) showed a morphology of these films which is highly conducive to the host–guest interaction. The presence of isolated micron-size domains, which were themselves composed of grains of several nm in diameter, was observed [54.49].

The molecular orientation in LB films of these novel substituted Pc derivatives was investigated by spectroscopic methods, including electron spin resonance, reflection adsorption infrared spectroscopy (RAIRS), polarised infrared (IR) spectroscopy and AFM. Amphiphilic mesogenic Pcs afforded the best films. These all contained a good degree of molecular order; furthermore, the type of molecular stacking in the films was found to depend upon the length of the side chains and the central metal [54.50].

Spin-Coating Method

The spin-coating method, designed for defining patterns on silicon wafers in integrated circuit (IC) technology, has now been adapted for deposition of thin organic films on suitable substrates [54.51]. Substrates are vacuum held onto the rotating chuck of a photoresist spinner. The spread solution was prepared in the same way as done for the LB deposition and a small volume of the solution is dispensed onto the rotating substrate surface from a microsyringe held at a distance of 5 mm above the spinner platform. A spinning time of 30 s for a solution concentration of 0.5–5.0 mg/ml is found to be sufficient in order to produce a uniform, homogeneous film. The rotation speed is normally varied between 1000–6000 rpm and the speed of spin and the concentration of solution

largely determine the thickness of the resulting films. The dependence of the film thickness d on spin speed ω and time t may be written in terms of an empirical expression [54.52]:

$$d = \frac{C}{\sqrt{t}} \omega^{-x}, \quad (54.1)$$

where C depends upon the evaporation rate of the solvent, and the viscosity and density of the solution. The index x is predominantly determined by the evaporation rate of the solvent. If the evaporation of the solvent is independent of the spin speed, x takes on a value of 2/3. For most solvents used, the evaporation varies with $\sqrt{\omega}$ and x becomes 1/2. A value of $x = 1$ is a valid approximation for slow evaporation [54.53, 54].

Spin coating is a simpler and more cost-effective method than LB deposition and also there is no requirement for the molecules to be amphiphilic. The LB technique, however, provides more precise control over the film thickness [54.55]. Both spun and LB thin films of an octa-alkyl-substituted phthalocyanine molecules displayed similar characteristic features in their optical absorption spectra. The appearance of Davydov splitting and the XRD pattern indicated the same crystallinity of the films [54.56]. Different physical structure and molecular packing may result from the use of different wet techniques. For instance, asymmetrically substituted OC molecules (Fig. 54.5) were deposited by LB and spin-coating techniques. XRD patterns and UV–VIS spectra of these films indicated some degree of anisotropic ordering within the LB films compared to spun films [54.57]. The spin-coated films were, however, exceptionally smooth, even and free from crystallites. A noncompact spin-coated film of phthalocyanine molecules bearing one crown on ether ring exhibited faster response and reversal time than the well-ordered and tightly packed LB films [54.58].

Self-Assembled Monolayers (SAMs)

Self-assembled monolayers (SAMs) have attracted considerable interest because of their simplicity of preparation, stability and versatility. The introduction of due functional groups into SAMs allows changes of state and property on surface or interface. These attributes make SAM films attractive for the sensor technology [54.59, 60]. SAM films are formed via reaction of a functional group within a molecule with the surface of a solid substrate. The methoxy or trichlorosilylalkyl derivatives of molecules form weak bonds with hydroxyl groups and are suitable for the formation of a SAM on an oxide surface such as indium tin-oxide

(ITO) and glass (SiO_2) [54.61]. A monolayer layer can also be self-assembled on gold or silver substrates if the molecules are attached with thio or disulphides groups at one end [54.62]. In supramolecular aggregation during the self-assembly process, the interactions between the adsorbate molecules are as important as those between adsorbates and the surface. The size and aggregation pattern for the formation of supramolecular structures (J-aggregates) are controlled by changing the number of polar sulfonic groups of meso-tetra (4-sulfonatophenyl) porphine [54.63].

Much fundamental work on SAM films was initially undertaken with simple functionalised alkane derivatives [54.64]. In the case of alkylthiols on gold, it is well established that the monolayer films were densely packed with a high degree of order, with chains typically oriented at about 65° to the substrate surface. In recent years, work has been undertaken to include a single tether chain with thiol or disulphide derivatives for SAM formation on gold-coated glass substrates. The molecular orientation with respect to the gold surface was found to depend upon the different alkyl-connecting chain lengths and different macrocyclic peripheral side chains [54.65]. The core of substituted Pc molecules bearing mercaptoalkyl groups is not parallel to the surface if the tether chain is increasingly long. For sufficiently long tethers, the core becomes oriented almost normal to the surface [54.66]. SAM films of thiol-derivatised cobalt phthalocyanine complexes on gold electrodes was susceptible to destruction via oxidative and reductive desorption and their potential applications as a sensor were therefore limited [54.67].

Self-assembled ultrathin films have recently received considerable interest because they allow fabrication of supramolecular assemblies with tailored architecture and properties [54.68]. Multilayered films can also be built up by sequential deposition of polycations and polyanions based upon electrostatic attraction [54.69–71]. Alternate deposition of planar functional molecules meso-tetra (4-sulfonyl) porphyrin (TPPS_4) or copper phthalocyaninetetrasulfonic acid, tetrasodium salt (CuTsPc) and cationic bis (pyridinium) salt was made to produce a self-assembled multilayered film [54.72]. Multilayer assemblies of porphyrin and phthalocyanine were also prepared by alternating deposition of oppositely charged rigid planar molecules of sodium (phthalocyanine tetra-sulfonate)cobalt $\text{Na}_4[(\text{CoTsPc})]$ and tetrakis(N,N,N-trimethyl-4-anilinium) porphyrin cobalt $[(\text{CoTAP})]\text{Br}_4$ [54.73]. A further investigation of the C-11 Pc derivative SAM has shown that the monolayer film was stable, exhibiting no oxidation and

only minor orientation changes on the gold surface over a period of 24 months as determined by infrared and fluorescence spectroscopy. The long active life of the Pc SAM was thought to be due to the macrocyclic ring possibly preventing oxidation of the thiolate root [54.74].

54.3.2 Thin-Film Properties

Surface/interface composition at the nanometre scale is believed to affect the organisation and chemical/physical properties of organic thin films. This long-range organisation determines both the optical and electrical properties of thin-film materials, leading to unique, new chemical sensor platforms. The overlap of π -electron wave functions from Pc molecule to Pc molecule is likely to occur between adjacent stacks in a thin-film form, giving rise to the broadening of energy levels [54.75].

Phthalocyanine Films

Phthalocyanines can exist in different polymorphic forms: α and β are among the most common. Both forms possess the herringbone structure for the stacking arrangement. The angle between the stacking axis and the normal to the molecular plane depends upon the method of preparation, types of phthalocyanine (metallo or metal-free) and substituents. For example, this angle is generally 25° and 45° for the α and β phases, respectively [54.76]. A typical absorption spectrum in the UV–visible range is shown in Fig. 54.3 for a substituted metal-free phthalocyanine (HPC) deposited on a glass substrate (similar to one shown in Fig. 54.2). The Q absorption band of the LB film was broader than one for the chloroform solution and appeared at the wavelengths between 650–800 nm. The Davydov splitting became apparent when compared with the spectra for the molecules in chloroform. The film forming properties and the stack order were both found to be influenced by the chain length of the ring substituents [54.77, 78]. An analysis into the in-plane molecular arrangements in the LB films of Pc compounds with short and long alkyl chains was performed by decomposing the absorption spectra into Gaussian–Lorentzian components. Long-chain molecules were found to be organised in a herringbone structure leading to the Davydov splitting of the Q-band. For short-chain molecules, the largely broadened blue component of the Davydov doublets was suppressed possibly due to the domination of an anisotropic stack-like molecular arrangement in LB films [54.79]. Characteristic Q-bands observed at about 630 nm in the UV–VIS spectra of the self-assembling monolayers (SAMs) of 2,9,16-Tri(tert-butyl)-23-(10-

mercaptodecyloxy)phthalocyanine and its disulfide on gold substrates were broadened and blue-shifted relative to those observed in solution [54.80]. The formation of high-quality Langmuir–Blodgett films of copper and nickel phthalocyanine derivatives substituted with short branched chains is reported. Ellipsometric and polarised optical absorption measurements suggest that the phthalocyanine molecules have a preferred orientation, with their large faces perpendicular to the dipping direction and to the substrate plane [54.81].

Electrical properties of **Pc** molecules are very dependent upon the doping and the nature of the substituents in the macrocyclic. Copper(II) tetrasubstituted phthalocyanine complexes, **CuPcX** (where $X = -\text{NO}_2$, $-\text{NH}_2$, $-\text{SO}_3\text{H}$, and $-\text{OH}$) exhibited an improvement of conductivity by five orders of magnitude over its unsubstituted counterpart. Further enhancement in conductivity was achieved by iodine doping. This increase in conductivity was attributed to the possible decrease in the metal–metal bond distance [54.82]. The effect of oxygen on charge transport was investigated by measuring the time-dependence behaviour of the film conductivity of zinc **Pc** (**ZnPc**) layers at a stable pressure of about 0.1 mbar of air and it was found that the conductivity gradually decreased by an order of magnitude with time. The conductivity reached saturation within several minutes for the film thickness smaller than 500 nm whereas similar electrical degradation in a 7- μm -thick film required more than half an hour. This thickness-dependent decrease in conductivity was caused by the velocity of the oxygen out-diffusion processes in the films [54.83]. The effect of doping on conductivity of a thermally deposited composite film of α -nickel phthalocyanine (**NiPc**) and the strong electron acceptor tetracyanoquinodimethane (**TCNQ**) was investigated by exposure to air. The doping took place at a much faster rate in the composite than in **NiPc** films. Values of 1.3 eV and 1.9 eV for the activation energy were obtained for devices incorporating **TCNQ** and the non-**TCNQ** devices, respectively, and the conductivity of the composite film was therefore found to be 20 times larger than the **NiPc** film [54.84]. Due to the excellent ability to photogenerate free charge carriers, the conductivity of the metal phthalocyanine (**MPc**) film is increased considerably as it can be seen from Fig. 54.4 showing the dark and illuminated current–voltage characteristics of a 10-nm-thick spun nickel phthalocyanine (**NiPc**) sandwiched between two metal electrodes.

Phthalocyanines of rare-earth metals primarily occur in the form of bisphthalocyanines with a sandwich-type structure and the cation is eightfold coordinated to the

two macrocycles. One of these phthalocyanine rings is virtually planar while the other is significantly distorted [54.85]. The Q-band in the absorption spectra of spun films of substituted lutetium bisphthalocyanine molecules becomes broader and red-shifted compared to the molecules in chloroform solution. Heat treatment of the film at temperature above 120 °C introduced molecular ordering, possibly due to the edge-to-edge interaction between neighbouring **Pc** moieties [54.86]. All these factors have led to successful formulation of phthalocyanines as chemically sensitive membranes for environmental monitoring [54.87–91].

Porphyrin Films

Inherent stability, unique optical properties and synthetic versatility of porphyrins and metalloporphyrins are exploited in sensor applications. Synthetic porphyrins and metalloporphyrins incorporated into polymers, glasses and Langmuir–Blodgett films matrices are used for detection of NO , CO_2 and O_2 because of the ability of heme to bind these gases. Metalloporphyrin sensing arrays have been used for the detection of organic odourants, such as amines, thiols and phosphines [54.92]. Porphyrins also combine readily with metals, coordinating with them in the central cavity. Many gas sensors take advantage of analyte binding to the centre metal atom in the porphyrin ring and a detectable optical change occurs as a result. In particular sensing properties of iron, zinc, copper, nickel, and cobalt containing porphyrins have now been studied [54.93–96]. The porphyrin rings of a thiol-derivatised cobalt (II) 5,10,15,20-tetrakis (4-tert-butylphenyl)-porphyrin (**CoTBPP**) molecules were immobilised on the surface of a 4-aminothiophenol (4-ATP) self-assembled monolayer (**SAM**) on gold (111) by in situ axial ligation. The reconstruction of the herringbone structure took place probably due to adsorption/desorption processes of molecules [54.97].

Substituents have considerable effects on the structure of porphyrin monolayers; for example the interaction between the porphyrins deposited on the **ITO** substrate without bulky tert-butyl groups was much stronger than that of the porphyrins with bulky tert-butyl groups [54.98]. Hybrid molecule-silicon capacitors were formed by attaching [5-(4-dihydroxyphosphorylphenyl)-10,15,20-trimesitylporphinatozinc (II)] porphyrin complexes to silicon oxide via a phosphonate linkage and the presence of multiple distinct peaks in electrical characteristics were associated with oxidation and reduction of the molecular monolayer [54.99]. Multilayered thin films of

porphyrins bearing bulky alkoxyphenyl substituents at two of the four meso-positions and phenyl phosphonates at the other two were deposited on the ITO substrates using the zirconium phosphonate linkage. Molecular aggregation was prevented by the addition of sterically demanding 2,6-di(n-hexoxy)phenyl substituents to the meso-positions of the porphyrin skeleton. The com-

pounds were able to form thin films without the presence of large molecular chromophore interaction relative to sterically unhindered porphyrins [54.100]. Highly conducting tetra-ruthenated cobaltporphyrin (Co (TRP)) and tetrasulfonated zincporphyrin (Zn (TPPS)) multi-bilayer films were prepared by electrostatically assembly for sensor applications [54.101]

54.4 Sensing with Phthalocyanine and Porphyrin

The interaction of reactive gases such as O₂, NO₂ and NH₃ with the phthalocyanine group of compounds has been shown to result in conductivity changes of these compounds. This effect was associated with charge transfer between the electron-donating phthalocyanine molecule and the electron-accepting gas [54.102].

54.4.1 Amperometric Sensor

The action of the oxidising gases O₂ and NO₂ and the reducing gases NH₃ and H₂ diluted in N₂ on the electrical conductivity of thin layers of zinc hexadecafluorophthalocyanine (ZnF₁₆Pc) and zinc phthalocyanine (ZnPc) was investigated. The conductivity ZnF₁₆Pc increased in the presence of NH₃ whereas ZnPc exhibits no sensitivity to this gas. The sensitivity to H₂ was higher for ZnF₁₆Pc than for ZnPc. This behaviour was related to the redox potentials of the two phthalocyanines [54.103, 104].

Response and recovery times for LB CuTTBPc films on platinum IDE are shown in Fig. 54.7 for different gas concentrations of 1–5 ppm. These times were determined from a model based upon the kinematics of adsorption and desorption of NO₂ gas molecules. It was found that recovery times were longer than response times, irrespective of gas concentration. The response time constant varied in the range 105–159 s. Repeated exposures to NO₂–air mixtures resulted in gradual degradation of reproducibility. The response was also believed to be influenced by the past history of the exposure of the sensor to the NO₂ gas, if the recovery time constant was longer than the switch-off time. These factors show that CuTTBPc is a material that is suitable for fabricating a disposable *single-shot* NO₂ sensor for practical uses [54.105]. LB films of an asymmetrically substituted phthalocyanine, 1,4-bis (4-hydroxybutyl) 8,11,15,18,22,25-hexaethylphthalocyanine molecules showed selective responses to 1–5 ppm concentrations of NO₂ at the room

temperature. Moisture had no effect on the response because of the hydrophobic nature of the alkyl groups. Exposure to Cl₂, NH₃, SO₂ and CO at ppm levels produced no measurable response [54.106]. Further work on the LB films showed that the NO₂ response was larger for the LB film produced by dipping the substrate perpendicular to the electrode finger than those dipped parallel to the fingers. This preferential behaviour was attributed to the ease of conduction along the long chains [54.107]. LB films of meso,meso'-buta-1,3-diyne-bridged Cu(II) octaethylporphyrin dimer molecules were used to fabricate amperometric sensors operating temperature of 90 °C. LB multilayers were reported to be selectively sensitive to small concentrations of NO in air without being affected by the contemporary presence in NO₂, CH₄, C₂H₅OH and CO [54.108].

Thickness, operating temperature, doping and post-deposition treatment of sensing membranes all affect the sensor performance. Vacuum-deposited CuPc of thickness 50–400 nm onto gold IDEs on glass substrate were

Fig. 54.7 Response (broken line) and recovery (solid line) of a 15-layer LB film of CuTTBPc when exposed to NO₂ periodically at 2-min intervals at 1, 2, 3, 4 and 5 ppm levels in succession

exposed to NO₂ gas of concentration 10–100 ppm. The film thickness had little effects on the room-temperature sensitivity, but the recovery ratio decreased with increasing film thickness. Thicker films showed improved recovery at 100 °C [54.109]. Due to the tetra-tert-butyl substitution on the periphery of phthalocyanine, CuTTBPc films have a larger lattice spacing, higher film resistance. Sublimed film CuTTBPc film showed a higher recovery ratio in the NO₂ sensing experiments [54.110].

NO₂ and O₂ treatment of evaporated CuPc films that were 160–200 nm thick on IDE improved the sensitivity and recovery time when exposed to 0.5–5 ppm of NO₂ gas. A Langmuir behaviour was predicted for the adsorption/desorption processes on the weakly binding surface sites of NO₂-treated CuPc films having a single activation energy [54.111]. When the CuPc films were subjected to post-deposition treatment by cooling down to 77 K, the mechanism of NO₂ adsorption, however, followed the Elovich model [54.112]. 100-nm-thick CuPc and iron Pc (FePc) films were heat treated at 240 °C under vacuum and then the responses of the films to the exposure of NO₂ in the 8–12.8 ppm range were monitored. The CuPc films were transformed to a stable β -phase and the adsorption occurred on the ligand rings. NO₂ was, on the other hand, adsorbed on both the ligand ring and the central ion of the FePc films [54.113]. An amperometric sensor was fabricated using the spun film of tetra-iso-propoxyphthalocyaninato copper (II) (i-Pro-CuPc), and the response, recovery and cyclic properties of the sensor were very temperature sensitive. The results showed ideal gas sensitivity at 65 °C and a good linear relationship existed between the resistance of gas sensor and the concentration of NO₂ [54.114]. 25-nm-thick NiPc films were deposited between the source and the drain of a field-effect transistor (FET) and the change in the drain current exhibited a linear dependence on the ozone concentration in air, in the range 0–150 ppb [54.115, 116].

Water-soluble copper phthalocyanine tetrasulfonate (CuTsPc) molecules were alternatively self-assembled with a bipolar pyridine salt on a 3-mercaptopropionic-acid-modified Au electrode to produce copper ion-selective electrodes (ISE). These ISE were found to have low resistance, short conditioning time and fast response. The electrode potentiometric response showed selective potentiometric response to Cu²⁺ ion in the range from 1×10^{-5} – 1×10^{-1} M, independent of the pH of the solution between pH 1–5. The response was dependent on the nature of the medium and the detection limit was found to be 7×10^{-6} M in acetate buffer

(0.2 M, pH 4.5) [54.117]. Carbohydrates were detected by flow-injection analysis at the water-soluble cobalt phthalocyanine tetrasulfonate (CoTsPc)-modified electrode with high sensitivity. Detection limits obtained in this manner range from 150 pmol injected for glucose and fructose to 600 pmol injected for maltose and sucrose [54.118].

54.4.2 Optical Sensors

The amperometric approach generally suffers from long response times and their use is restricted due to possible fire and explosion hazards caused by electrical power. Organic systems are also prone to slow degradation arising from the chemical reactivity of charge carriers. Optical transduction techniques, on the other hand, offer high speed, high precision, immunity to interference, and remote sensing capabilities for detection of trace gas species.

Optical Absorption and Fluorescence Spectra

Optical transmittance of thermally evaporated lead phthalocyanine (PbPc) and nickel phthalocyanine (NiPc) thin films changed on exposure to NO₂ in the IR region of the optical absorption spectrum [54.119]. The disappearance of Davydov splitting from the UV–VIS absorption spectra of 20-layer-thick LB films of 1,4-bis(4-hydroxybutyl)-8,11,15,18,22,25-hexakisdecyl phthalocyaninato copper molecules was observed when

Fig. 54.8 The dependence of the refractive index of octa-substituted phthalocyanine on the wavelength before and after exposure to 90-ppm NO₂ gas for 30 min. The recovery was examined after flushing of the LB films with N₂ for 30 min

the films were exposed to 100 ppm of NO₂ [54.120]. The local interaction between the central metal atoms and NO₂ distorted the herringbone structure. Gas adsorption and desorption processes were described by exponential functions, both characterised by a single time constant. The dispersion relation in Fig. 54.8 for the refractive index was obtained by using simple Kronig–Krammer transform of absorption spectra of the LB thin film of another octa-substituted metal-free phthalocyanine molecules. The full recovery of the refractive index to its original value was achieved after flushing with the N₂ gas for wavelengths larger than 782 nm. Ellipsometry measurements on thin films of tetrasulfonated copper phthalocyanine showed increases in the real and the imaginary parts of the dielectric constant on exposure of NO₂ gas possibly due to the rise in the density of dipoles and higher absorption, respectively [54.121].

LB films of 5,15-bis(4-aminophenyl)-10,20-bis[3,4-bis(2-ethylhexyloxy)phenyl]-21H,23H-porphine were prepared at a dipping rate as high as 500 mm/min and an inhomogeneous structure was obtained with high porosity. These porphyrine films showed much faster response to 4.6 ppm of NO₂ gas and a sensitivity of 60% relative absorbance change at 439 nm was achieved. Full and accelerated recovery of the original spectrum was also achieved by gentle heating at 353 K. The sensor was reported to have a self-life as long as one year [54.122]. Kinetic UV–VIS spectroscopic measurements were made on a porphyrin-entrapped sol–gel film for NO₂ sensing. The method was capable of detecting levels as low as 176 ppb of NO₂ at room temperature and showed a fast and fully recovery [54.123].

The blue colour of rhodium phthalocyanine LB films becomes transparent upon chlorination. A pronounced quenching of the characteristic triplet centred on the Q-absorption band took place at 662 nm, but the absorption band in the near UV part of the spectrum remained almost unaffected. Optical spectra partially recovered when the exposed film was left in air for several hours. Overall effects of chlorination (quenching and recovery) depended on the period of exposure [54.124]. LB gadolinium phthalocyanine films were exposed to 10 ppm of chlorine and changes in optical absorption spectra were observed as a result of the oxidation of the film by chlorine to form [Gd(Pc)₂]⁺ species. The kinetics of such changes were described by a polyfunctional process with different decay time constants and the effects were found to be highly reversible [54.125].

SAM films are of interest because the chemically bound monolayer is intrinsically more robust than LB

films and the response times are also expected to be faster. Monolayers of diphtalocyanine disulfide Pc molecules were self-assembled on gold-coated glass substrates with the Pc macrocycle oriented parallel to the metal surface. Changes of the reflectivity signal were observed on exposure to NO₂ gas in proportion to the concentration [54.126]. The fluorescence emission spectrum of each of the Pc SAMs was obtained by exciting each monolayer along the longitudinal axis of the optical waveguide via laser-induced evanescent-wave stimulation. The use of the longer mercaptoalkyl connecting chain appeared to inhibit quenching of the electronically excited state through energy transfer to the metal layer. Fluorescence response to 10 ppm NO₂ was found to be selective with no interference from CO and CO₂ [54.127].

Surface Plasmon Resonance Technique

The surface plasmon resonance (SPR) technique is based on the excitation of surface electromagnetic waves of transverse magnetic (TM) modes travelling along the interface between a metal and a dielectric medium. Using a semicylindrical prism of high refractive index n_p in Kretschmann's configuration, as shown in Fig. 54.9, these waves are excited by a p-polarised light of wavelength λ via the evanescent field [54.128]. The evanescent field will be completely attenuated at a particular angle of incidence corresponding to resonance and there will be no reflection. Figure 54.10 shows the SPR results when a spun film of nickel(II) tetrakis(4-cumylphenoxy)phthalocyanine (NiPc) molecules was subjected a sequence of exposure to ozone (O₃) at 2 ppm. The period of 20 mins was allowed for the film to recover to its original state. The shift of the resonance angle $\Delta\theta_a$ was believed to be caused by a change in the refractive index of the film due to the interaction of O₃. $\Delta\theta_a$ is

Fig. 54.9 A Kretschmann-type configuration to measure SPR data of CA thin films

Fig. 54.10 The effect of a sequence of exposure at 20-min intervals of 2-ppm O_3 on a NiPc spun film. The broken line represents the system prior to exposure

usually written in the form [54.129]:

$$\Delta\theta_a = \frac{(2\pi/\lambda)(|\varepsilon_m|\varepsilon_i)^{3/2}d}{n_p \cos\theta(|\varepsilon_m| - \varepsilon_i)^2\varepsilon}(\varepsilon - \varepsilon_i), \quad (54.2)$$

where $|\varepsilon_m|$ is the modulus of the real part of the dielectric constant of the gold film; ε_i is the dielectric constant of the medium (air in this case) in contact with the organic thin layer of thickness d and the dielectric constant ε . The resonance minimum moved to an increasingly larger angle after each exposure to ozone. The half-width became narrower at the same time and this was believed to be the consequence of oxidation of the phthalocyanine ring by ozone, which resulted in bleaching of the dye. SPR responses are in general slower and less readily reversible than semiconductivity changes but the technique is capable of providing additional information on the interaction between the gas and films as the shifts in both the angle and depth of the resonance can be monitored. Experimental data from the SPR response of CuPc films to nitrogen dioxide were input to a design process using an evolutionary algorithm. 25-nm-thick gold layers were found to exhibit 42.9% greater contrast than layers with a thickness of 50 nm. Using evolutionary design predictions, further modifications could be tested for available materials, and redundant layers might be eliminated. By inclusion of the external optics, a design could be selected to accommodate poor precision ($\pm 0.5^\circ$) in the incident angle and a possible multi-layer solution was shown using Teflon AF 1600, with a refractive index similar to 1.3. The predicted NO_2 response showed an improvement compared with the classical SPR configuration, and the incident angle chosen by the genetic algorithm for the interrogation of these

layers was close to a stationary point in the absolute response curve [54.130].

Figure 54.11 shows the transient response when thick films of copper hexadecafluorophthalocyanine ($CuPcF_{16}$) were exposed to 100 ppm of NH_3 for 2 min followed by the injection of dry air for a further 2-min period. The film was exposed to 200 ppm of NH_3 for the next cycle. The SPR response was very rapid and the recovery was complete. Unsubstituted CuPc was practically insensitive to this gas. Strong electron-withdrawing fluorine substituents made this substituted compound sensitive to reducing gases such as NH_3 [54.131].

SPR experiments were performed on films of different phthalocyanine derivatives in order to investigate the interaction mechanism with NO_2 . SPR signal concentration as low as 1 ppm was measured using spun films of crown-ether-substituted phthalocyanines and octa-3,7,11-trimethyldodecyloxy phthalocyanine [54.132]. Adsorption of NO_2 took place both on the surface of the film and into the bulk. The surface adsorption increased the film thickness while the change in the real part of the film refractive index occurred due to the diffusion of NO_2 into the LB film. These processes were reversible and had no effect on the optical absorbance of the LB film. The SPR response of the bare Ag film to the exposure of NO_x (the equilibrium mixture of nitrogen dioxide and dinitrogen tetroxide) was slightly slower than the LB films of tetra-4-tert-butyl-phthalocyanitosilicon dichloride (ttb-PcSiCl₂/Ag) system. This effect was associated with the high affinity of the phthalocyanine to NO_x

Fig. 54.11 Kinetics of the SPR response of copper hexadecafluorophthalocyanine ($CuPcF_{16}$) film to NH_3 gas at 100 ppm and 200 ppm. Measurements were at a fixed angle of $\theta^* = 46^\circ$

gas. The NO₂ gas was also able to reach the Ag/Pc interface film and the reaction with the metal film resulted in the growth of a surface layer. This irreversible effect was found to be predominant during the recovery cycle and considerably reduced by the presence of a buffer LB layer of ω -tricosenoic (ω -TA) acid [54.133]. SPR studies showed that exposure of thin films of 18-crown-6 metal-free phthalocyanine molecules to NO₂ decreased the film absorbance. The optical permittivity of the NO₂-treated Pc over-layer was regarded as being an average of the optical permittivities of both components since the optical fields associated with surface plasmon polaritons sampled both the Pc and the NO₂ molecules. The disruption in the charge conjugation of the phthalocyanine molecules was observed because of the generation of organic radical cations as end products of the charge transfer during the physisorption process [54.134].

Using the excitation at wavelengths of 488 and 632.8 nm, SPR measurements were made on LB films of porphyrine molecules of EHO type deposited on an Ag-coated glass substrate. The resonance shift observed was larger at 488 nm than at 632.8 nm when the EHO films were exposed to NO₂ gas. The thickness and the complex dielectric constants at 632.8 nm were attributed to the island structure of the EHO LB films but the derived properties at 488 nm were believed to be caused by dispersion due to optical absorption [54.135]. Similar results were further obtained from UV-VIS absorption in these films [54.49].

54.4.3 Detection of Volatile Organic Vapour Compounds

Phthalocyanine molecules have also been extensively investigated for the recognition of volatile organic compounds (VOC). Langmuir-Blodgett (LB) and evaporated films of lutetium bisphthalocyanine (LuPc₂) molecules were deposited on indium tin-oxide (ITO) interdigitated electrodes in order to study the changes in their conductivity at room temperature due to the presence of a variety of organic vapours with different chemical functionalities. The results demonstrated the viability of the phthalocyanine thin films as the active species for systems specifically designed for the monitoring of aromatic components in food. The majority of the work on vapour sensing has, however, been based upon quartz crystal microbalance (QCM) transduction techniques. The frequency shift Δf from the nominal resonance frequency f_0 of the crystal due to the change in the mass Δm due to the adsorption of the vapours

is [54.136]:

$$\Delta m(\text{mg}/\text{cm}^2) = \frac{\Delta f(\text{Hz})}{2.26 \times 10^{-6} f_0^2}. \quad (54.3)$$

It was demonstrated that monomeric soluble transition-metal phthalocyanines R₄PcM (R=tert-butyl or 2,2-dimethyl-3-phenyl-propoxy) used as sensitive coatings for quartz microbalance transducers show reversible interaction and high sensitivity for organic solvents with high boiling point [54.137]. Quartz microbalance devices coated with LB films of copper(II) tetra-(tert-butyl)-5,10,15,20-tetraazaporphyrin exhibit good sensing response to the vapour of benzene and toluene at room temperature [54.138]. Soluble tetrakis-hexyl- and dodecylthiophthalocyaninato nickel(II) and the corresponding Pd(II) and Ag(I) complexes were investigated as sensitive materials for the detection of organic solvent vapours using quartz microbalance and interdigitated capacitance transducers. Sensor responses were found to be reversible at room temperature with response times on the order of several seconds depending on the partition coefficients of the organic solvents in the phthalocyanine film [54.139]. LB films of lanthanide diphthalocyanines such as praseodymium, ytterbium as well as octa-tert-butyl praseodymium diphthalocyanines were known to display spectroscopic changes when exposed to tobacco smoke [54.140]. The sensitivity and partition coefficient for ethanol, dichloromethane, acetone, and *n*-hexane were found to be larger for the QCM sensor using thermally annealed ordered membranes of octa(13,17-dioxanonacosane-15-sulfanyl)-substituted mesomorphic nickel(II) phthalocyanine molecules than as-coated untreated films. It was found from Raman spectroscopy that molecules with saturated C—C bonds such as ethanol interact with phthalocyanine films predominantly by the formation of hydrogen bonds and the sensor response to π -bond-containing compounds such as acetone is the result of their π - π interaction with the conjugated phthalocyanine ring [54.141].

Changes in refractive index of lutetium bisphthalocyanine (LuPc₂) in the presence of ethanol, hexanal, *n*-butyl acetate and acetic acid were successfully exploited to produce an optical-fibre sensor operating at the wavelength of 1310 nm, capable of monitoring changes up to 10 dB in the reflected optical power for the detection of an 88-mmol/l concentration of acetic acid [54.142]. UV-VIS spectra of spin-coated layers of 29H,31H-(2,4-di-*t*-amylphenoxy)phthalocyanine, Zn(II) tetra-4-(2,4-di-*t*-amylphenoxy)phthalocyanine and Zn(II) tris-(2,4-di-*t*-amylphenoxy)-[4-(4-mercapto

-phenylimino-methyl)-phenoxy] phthalocyanine were found to be sensitive to tert-butylamine, diethylamine, dibutylamine, 2-butanone and acetic acid. The selectivity was determined by both the metal and the peripheral substituents [54.143]. The synthesis of specially designed bisphthalocyanine derivatives for VOC detection has been reported and their UV spectra are selectively sensitive to vapours depending on both the metal and the peripheral substituents. This observation has led to the fabrication of an *electronic optical nose* using an array of as-manufactured sensors for the analysis of some volatile organic compounds (VOC) that are of interest in food analysis [54.144].

The electrical conductivity of sol-gel-derived spun hybrid cobalt porphyrin-SnO₂ thin films showed fast and reversible response to methanol vapours; the highest responses were observed at 250 °C. The porphyrin was thermally stable up to 300 °C within the SnO₂ ma-

trix and enhanced the methanol detection sensitivity at lower working temperatures. The incorporation of porphyrin into SnO₂ film had no effect on the detection of CO [54.145]. Hybrid thin films were produced using porphyrin and phthalocyanine and the response of absorption bands of the blend systems to the presence of VOCs was different from that obtained with a single compound [54.146].

Toluene vapour sensing has been successfully demonstrated using LB films prepared from copper tetrakis-(3,3-dimethyl-1-butoxycarbonyl) phthalocyanine (CuPcBC), copper tetrakis-(3,3-dimethyl-1-neopentoxycarbonyl) phthalocyanine (CuPcNC) and nickel tetrakis-(3,3-dimethyl-1-butoxycarbonyl) phthalocyanine molecules. Exposure to toluene resulted in a partially reversible shift in the resonance depth and position of the SPR curves and toluene could be detected down to at least 50 ppm [54.147].

54.5 Polymeric Materials

A polymer comprises of repeating molecules with the same chemical structure. The electrical conductivities of the intrinsically conducting polymer systems now range from 10^{-10} – 10^{-5} S/cm. The common electronic feature of pristine conducting polymers is the π -conjugated system, formed by the overlap of carbon p_z orbitals and alternating carbon-carbon bond lengths. Doping of the polymers can increase the conductivity to as high as 10^{+4} S/cm, a value comparable to that of a metal.

54.5.1 Conducting Polymers

Figure 54.12 shows the chemical structure of a few commonly used conducting polymers such as polyaniline, polypyrrole, and polythiophene for chemical sensors. In addition to the deposition techniques described earlier, conducting sensing filaments were produced using the scribbling and platinum-wire techniques [54.148]. Sensing membranes were also formulated by laser-induced chemical vapour polymerisation [54.149].

LB films of stearic acid, a polyaniline oligomer (16-mer) and polypyrrole were deposited on the IDEs. Composite films of polyaniline and polypyrrole mixed with stearic acid in equal ratio by weight were also deposited on similar electrodes. Different brands of min-

Fig. 54.12 Chemical structures of typical conducting polymers for sensors

eral water, tea and coffee were sensed by impedance measurements on the films over the frequency range of 20–10⁵ Hz. The sensor arrays composed of these films were able to differentiate tastants below the human detection threshold [54.150]. The Brunauer, Emmett and Teller (BET) surface area for an amperometric polyaniline/Au/Nafion[®] sensor prepared by the cyclic voltammetry (CV) method was found to be higher than structures prepared by the constant current (CC) method; the maximum sensitivity of CV-fabricated NO₂ gas sensors was 3.04 μ A/ppm [54.151].

The type of doping is known to influence conducting-polymer-based sensors. Composite polyaniline emeraldine salts doped with an inorganic metal complex dopant, chromium(III) trioxalate (CTO) were produced by the chemically oxidative polymerisation method. Polyanilines were also electrochemically doped with naphthalene-1,5-disulphonic acid (NSA). The conductivities of these materials were monitored by using the four-probe method when pellets of these materials were exposed to several saturated vapours of organic solvents for 30 min; the results are summarised in Fig. 54.13. The conductivity of the CTO-doped pellets was reduced by 18% on exposure to CH₂Cl₂ whereas the exposure had no effect on NSA-doped material. The response of undoped composite polyaniline salt to CH₂Cl₂ was also very small. NSA-doped pellets, on other hand, showed a significant change in conductiv-

ity on exposure to CCl₄, while only very small changes were observed for the two other polymers. The responses to dimethylsulfoxide (DMSO) and N-methylpyrrolidone (NMP) were consistently higher for all three materials than the responses to the solvents CH₃CN and methanol (MeOH). It became apparent that the interaction of solvents with the polyaniline salt became stronger with increasing polarity of the solvents. The response was reversible for all three materials. The nature of the dopant in the material and the consequent change in polarity, especially at the dopant site, and the resultant effect on π -electron delocalisation and conductivity are primarily responsible for the characteristic sensing ability of the materials [54.152]. Extruded polymer blends containing polyaniline doped with dodecyl benzene sulfonic acid were dispersed in polystyrene (PSt) matrix filaments and the electrical conductivity of these filaments increased by a few orders of magnitude when exposed to a homologous series of alcohols, including methanol, ethanol and 1-propanol. The effect was reproducible and recovery was satisfactory. The sorption of analyte molecules was believed to facilitate conduction through the insulating PSt moieties by enhancing charge-carrier mobility through hopping processes between adjacent polyaniline particles [54.153].

Multilayered thin films of polypyrrole were prepared by modifying a preformed Langmuir–Blodgett (LB) film of stearic acid by exposure to gaseous reactants such as hydrochloric acid and pyrrole vapours. A change in the electrical resistance of the film was observed when the film was exposed to polar molecules such as methanol, ethanol and acetone, while the effect of nonpolar molecules on the resistivity of the film was found to be smaller. The response of LB films to exposure to ethanol was faster than that of electrochemically deposited polypyrrole, possibly due to the high ratio of surface area to bulk volume in the LB film [54.154]. Changes in mass and conductivity of polypyrrole thin films were measured to sense the primary alcohols [54.155].

Attempts have been made to integrate polyaniline optical sensor elements with optical communication technology for remote sensing by using 1300 nm as the operating wavelength. A 1% increase in transmission was observed at 1300 nm for electrochemically prepared polyaniline films when exposed to gaseous ammonia levels as low as 6 ppm at 50% relative humidity (RH). Different concentrations of ammonia were read by calibrating the sensors at intervals of 15 s. The response time was found to be insensitive to relative humidity variations in the range 30–70% [54.156].

Fig. 54.13 Effects of vapour of: (1) dichloromethane (CH₂Cl₂), (2) chloroform (CHCl₃), (3) carbon tetrachloride (CCl₄), (4) acetonitrile (CH₃CN), (5) methanol (MeOH), (6) dimethylsulfoxide (DMSO), and (7) N-methylpyrrolidone (NMP) on the conductivity of: (A) pristine polyaniline emeraldine salt, and the salt doped with (B) chromium(III) trioxalate (CTO), and (C) naphthalene-1,5-disulphonic acid (NSA)

Certain specially prepared polyaniline films showed partially reversible absorbance changes in the wavelength range 620–728 nm when exposed to 50–100 ppm of ozone at room temperature. The maximum sensitivity was attained at 620 nm. The cost-effective commercial exploitation of this effect was possible since the wavelength range was compatible with implementation on low-cost plastic optical fibres and small light sources [54.157].

Efforts have been invested in the use of information technology techniques to produce smart sensors. The sensor system, consisting of an acoustic two-port resonator operating at 433.92 and 380.8 MHz was configured as a frequency oscillator, including an integrated electronic module. The polymeric membranes were tested at room temperature for response to NO₂, NO, NH₃, CO, CH₄, SO₂, and H₂S in N₂. Responses to relative humidity (RH), and organic vapours (ethanol, acetone, and ethyl acetate) were also monitored. The sensitivity was found to be high. Principal component analysis (PCA) was performed to distinguish between different vapours of low concentrations [54.158]. Fluorescence emission from polymer-immobilised dye molecules on the multi-fibre tips was studied on exposure to organic vapours. Temporal responses were found to depend upon chemical nature (for example, polarity, shape and size) of both the vapour and the polymer; these were used as input signals to train a neural network for vapour recognition. The system was able to identify individual vapours at different concentrations accurately [54.159]. Similar work was reported using the solvatochromic dye, Nile red. The dye was immobilised within various polymers. The substrate played a role in determining the sensitivity of the sensor. The sensitivity attained with microstructure glass (MSG) substrates was seven times greater than that with SU-8 photoresist-coated glass substrate and a 50% faster recovery was also achieved with the MSG substrates. The MSG sensor array was able to fingerprint the response for separate analytes with a high degree of repeatability. Using pattern-recognition techniques, sensor arrays were adaptable for gas identification and discrimination ([54.160]).

54.5.2 Ion Sensing

Water purification requires calibration of metal-ion contents. Polymeric ion-selective electrodes (ISEs) for Pb²⁺ incorporating *N,N'*-bis(salicylidene)-2,6-pyridinediamine with 2-nitrophenyl octyl ether and 50 mol % lipophilic additive were reported to have rapid response and excellent selectivity towards lead

ions over other interfering metal ions [54.161]. *N,N'*-bis(5-methyl salicylidene)-*p*-diphenylene methane diamine formed a complex with Pb²⁺ and its selectivity was high, possibly due to the fact that the distance between the two nitrogen atoms and the position of the two hydroxyl group is matched with the size of Pb²⁺ ions. ISEs based upon a dispersion of this Schiff base compound into the polyvinylchloride (PVC) membrane were characterised by a fast response time, a wide linear dynamic range and a fair selectivity coefficient with a slope of 29.4 mV per decade. The sensor had a low detection limit and an active life of three months without displaying considerable divergence in potentials [54.162]. A cleaned gold microelectrode was soaked in the freshly prepared solution of *o*-amino thiophenol (*o*-AT) and the metal nitrate of Cu, Hg and Pb in *N,N*-dimethylformamide (DMF) for 4 h at room temperature. Simultaneous interaction took place between the thiophenol group of *o*-AT and the gold surface and its thiophenol and amino groups and M²⁺. The ratio of 4 : 1 was found to be appropriate for *o*-AT:M²⁺ for the self-assembly of the *o*-AT on the gold surface and the formation of recognition cavities. The prepared ISEs showed specific selectivity to the template metal ions in mixed solutions containing the three heavy-metal ions. The limits of detection for ISEs were found to be 1.46×10^{-8} M, 3.73×10^{-8} M and 4.34×10^{-8} M for Hg⁺⁺, Cu⁺⁺ and Pb⁺⁺ ions, respectively [54.163]. Membranes containing five-layer LB films of tetracarboxylic perylene derivative and polypyrrole molecules were able to detect trace levels of Cu²⁺ ions in water [54.164]. The thiol-Cu-SAM particles were doped by the adsorption of thioxyleneol or decanethiol into the porous polypyrrole film surface, resulting in an improvement in the sensitivity of the film to NH₃ [54.165]. Water-soluble regioregular polythiophenes containing acid C side chains were found to be suitable for the development of new Zn²⁺, Mn²⁺, and Cd²⁺ sensors [54.166].

54.5.3 Examples of Other Polymeric Sensors

A coordination polymer poly(CuMBSH) was formed via reaction of the bifunctional amphiphilic ligand, 5,5'-methylenebis (*N*-hexadecylsalicylideneamine) and copper ions at the water subphase. The response of LB films of poly(CuMBSH) to exposure of benzene, toluene, ethanol and water was monitored by SPR measurements. The film became swollen, possibly due to the diffusion of solvent vapour into the polymer film. Poly(CuMBSH) is regarded as a relatively nonpolar ma-

terial and its interactions were expected to be greater with vapours having a smaller dipole moment; the sensitivity increased with smaller dipole moment and higher refractive index of the vapour. The refractive index of the film increased because of an increase in the film density with the vapour filling the free volume inside the film. Similar results were obtained from admittance spectroscopic measurements on the same organic systems [54.167, 168].

The electrical properties of poly(methyl methacrylate) polymer (PMMA) films have been exploited for sensing applications (see Fig. 54.14a for the chemical formula). An increase in resistance of up to three orders of magnitude was observed for composite thin films of PMMA with carbon nanotubes when exposed to dichloromethane, chloroform and acetone. The sensing mechanism is explained on the basis of volume expansion and polar interaction of various vapours on

Fig. 54.14a,b Chemical structures of (a) poly(methyl methacrylate) derivatives and (b) reaction of polyphenyl-sulfide molecules with ozone

Fig. 54.15 Response of spun PMMA films on exposure to benzene (0 D), toluene (0.43 D), ethyl benzene (0.58 D) and m-xylene (0.62 D)

the nanotube surface [54.169, 170]. SPR measurements were made to investigate the room-temperature response of spun PMMA films to benzene, toluene, ethyl benzene and m-xylene (BTEX) vapours under dynamic conditions. The response of PMMA to benzene was fast and reversible. The dissolution of benzene in the bulk of the polymer film formed a heterogeneous layer, primarily giving rise to swelling of the film and the value of the partition coefficient was estimated to be 112. Figure 54.15 shows that the increase in angular shift per ppm was linear with decreasing dipole moment of the solvent vapours. Benzene is a nonpolar solvent and toluene, ethyl benzene and m-xylene are expected to show stronger solvation than benzene. Dissociated solvent ions may have formed a shell of bound ions and, as a result, the effective radius for dissolution in the polymer matrix would have increased. This dissociation might not easily occur for benzene, producing the highest SPR response [54.171]. A sensor has been made from a permselective poly(dimethylsiloxane) (PDMS) hollow-fibre membrane, showing a fast response time, very high oxygen permeability, and optimised oxygen/nitrogen selectivity. This sensor was suitable for monitoring the oxygen content in the outlet stream generated by medical oxygen concentration units [54.172].

Single-polyaniline films generally suffer from poor mechanical stability and polyaniline-blend films were prepared for practical applications using PMMA and PSt. The presence of water vapour, functioning as the interference gas, led to the lowering of the NH_3 response of the sensor in a humid atmosphere. The humidity effect was larger for PMMA than the PSt blend film. The difference was, however, not as large as expected from the water-sorption ability of PMMA [54.173]. The detection limits of ISE membranes with solid contacts are generally lower than a traditional liquid inner contact because of the diminished ion fluxes. Poly(methyl methacrylate)/poly(decyl methacrylate) (PMMA/PDMA) copolymer was employed as a solvent-cast membrane matrix on a layer of poly(*n*-octyl)thiophene (POT) deposited on Au as the internal contact. Ca^{2+} - and Pb^{2+} -selective electrodes were not sensitive to O_2 and the presence of a water film between the membrane and the internal contact was not found. The limits of detection were better by an order of magnitude and the response at low concentrations was much faster than for the liquid-contact electrode. For example, the drift was found to be smaller than 0.4 mV/min after 2 min when the concentration was increased from 10^{-9} to $10^{-7.7}$ M [54.174].

Fig. 54.16 Time-dependence behaviour of ozone sensitivity of PPS films. Two sets of hourly readings, separated by 16 h of continuous exposure without SPR measurements (dashed line)

An amperometric hydrogen sensor was proposed using a proton-conducting solid polymer electrolyte membrane (PEM), a blend of palladium and platinum as the anode and platinum as the cathode. The sensor operated as a fuel cell ($\text{H}_2/\text{Pd-Pt}/\text{PEM}/\text{Pt}/\text{O}_2$) and the short-circuit current was found to be linearly related to the hydrogen concentration [54.175].

It has recently been reported that thin films of polyphenylsulfide (PPS) (commercially termed noXon) act as efficient scrubbers of ozone from atmospheric ambient through the oxidation of the PPS molecules [54.176]. Thin films of this compound are found to be a useful material for the fabrication of

sensing membranes suitable for the detection of ground-level ozone at concentrations of a few ppm or even lower [54.177, 178]. A 1-h exposure to 2 ppm of O_3 was shown to cause at least a 1.1% change in the refractive index of the film [54.179]. As shown in Fig. 54.14b, oxidation of the PPS polymer by ozone exposure results in an irreversible increase in the index of refraction of the polymer [54.180].

Figure 54.16 shows the results of SPR measurements on PPS films when exposed to 1.5-ppm ozone. The increase in the refractive index Δn was found to be linear over the first few hours of exposure with an estimated slope of 1×10^{-4} refractive index units (RIU)/min. The sensitivity was defined as the ratio of Δn to the concentration of ozone. The interaction of O_3 with PPS films is believed to be an accumulative effect and such mechanisms can therefore serve as both a scavenger as well as an indicator of ozone in a certain ambient. The density of the binding of oxygen to a PPS film after five hours of exposure to 2-ppm ozone was estimated from QCM measurements to be about $5 \times 10^{18} \text{ cm}^{-3}$.

Electrospun nanofibers with diameters of 100–400 nm were deposited on the surface of a QCM by electrospinning homogenous blend solutions of cross-linkable poly(acrylic acid) (PAA) and poly(vinyl alcohol) (PVA). The NH_3 sensing properties were mainly affected by the content of the PAA component in the nanofibrous membranes, the concentration of NH_3 , and relative humidity. The sensitivity of nanofibrous-membrane-coated QCM sensors was also much higher than that of continuous-film-coated QCM sensors [54.181].

54.6 Cavitand Molecules

Thin films of some novel cavitand compounds such as crown ethers [54.182] and calixarenes [54.183, 184] can form inclusion complexes with some organic guest molecules. This effect is being extensively exploited for the development of sensors for organic vapours [54.185, 186]. Thin films can be prepared using LB film deposition, spin coating and self-assembly techniques [54.187–190]. The nanoporous flexible structure of thin LB films of amphiphilic calixresorcinarene derivatives are found to provide a suitable matrix for the incorporation of aromatic molecules [54.191]. This adsorption process was very fast, and full recovery of the film was observed after flushing with clean air. It has to be pointed out, however, that the detected vapours were

of a high concentration (a few percent by volume) and the adsorption was not selective since all vapours studied yielded a similar response. However, this may lead to the development of a sensor for explosives, where specificity is not considered relevant. These effects are attributed to weak and nonspecific interactions between the guest molecules and the calixarene LB film. It was also shown that the adsorption of organic vapours occurs in the whole bulk of the LB films, and that the number of adsorbed molecules is much higher than the number of calixarene molecules [54.192]. The adsorption mechanism involved the swelling of the film and even condensation of the adsorbate within the film. The swelling of the film was confirmed by independent

Fig. 54.17 Chemical formulae of calixresorcinarene derivatives

measurements using ellipsometric and surface plasmon resonance (SPR) techniques [54.193]; the adsorption mechanism remained still unclear. For all the studied analytes, the number of adsorbed molecules was found to be much larger than that expected from the geometrical dimensions of the intrinsic calixarene cavity and the empty space between the molecules. This discrepancy was explained by either film swelling or due to the condensation of vapour molecules inside the film, or both [54.191]. Spun films of calixresorcinarenes, however, were found to be homogeneous, and the porosity of the film was similar to that of LB-deposited films. Both LB and spun films of comparable thickness exhibited similar SPR response on exposure to toluene vapour [54.55]. Prolonged irradiation of the CA films with a focused laser beam caused an initial increase in film sensitivity to various organic vapours [54.194].

Figure 54.17 shows the chemical structure of an amphiphilic calixresorcinarene derivative with several different types of substituents. Exposures of layers of CAs to vapours of benzene, ethylbenzene, toluene and m-xylene in low concentrations produced changes in the optical properties, i. e., the film thickness and refractive index of the layers. Fast response and recovery processes have been observed, with response times as short as a few

seconds. The normalised SPR responses are shown in the three-dimensional (3-D) diagram in Fig. 54.18. It is apparent that the interaction of the analyte was, in general terms, specific to the thin film of a particular CA derivative. The adsorption mechanism was interpreted in terms of the accumulation of the vapour molecules in

Fig. 54.18 A 3-D representation showing the response of different calixarene derivatives to different organic vapours (benzene (B), m-xylene (X), toluene (T), and ethylbenzene (E)) at a concentration of 375 ppm

the liquid phase inside the film matrix, probably caused by capillary condensation in the porous structure of the CA films [54.195]. These LB films had a characteristic pore size of about 1 nm. Condensation of vapour occurred inside capillaries similar to the porous structure of calixarene films at pressures lower than their saturated pressure at a certain temperature. The saturated vapour pressures of ethylbenzene and m-xylene are similar and therefore their exposure to the CA derivatives produced similar effects. Benzene on the other hand, with its highest saturated vapour pressure, yielded the smallest detectable SPR signal.

Composite LB films of amphiphilic CA and PPS were exposed to 2 ppm of O₃ [54.177]. The competition between the permanent oxidation process of the PPS polymer by the adsorbed O₃ molecules and the release of O₃ from the CA matrix was found to depend on the molar ratios of the CA and PPS compounds. Recovery became slower with lower CA proportions in the film matrix.

54.7 Concluding Remarks

The scope of organic materials for chemical sensing is huge and it is impossible to provide a complete description of these materials. Electronic artificial noses are being developed as systems for the automated detection and classification of odours, vapours and gases. These instruments consist of three main components: (i) an array of chemical membranes (ii) electronic circuitry for data acquisition, signal processing and display and (iii) a pattern-recognition algorithm. Up-to-date information on applications of materials for electronic noses and tongues is available in a recent review [54.197]. Problems associated with human senses are many: individual variability, impossibility of online monitoring, subjectivity, adaptation, infections, harmful exposure to hazardous compounds, and mental state. These limitations can be overcome by developing intelligent sensor systems. Gas sensors tend to have very broad selectivity, responding to many different analytes of varied concentrations. The electronic nose/tongue, therefore, offers a definite advantage in many applications in the food and utility industries, the health care and medical care sectors, and security services. The demand for advanced electronic noses will continue to stimulate the search for novel sensing materials.

Mathematical and computational tools are expected increasingly to play a part in the design of advanced

The conductivity of the CA derivative is intrinsically low. CA films were deposited on the gate between the source and the drain of a charge-flow transistor and the turn-on response for the transistor upon exposure to organic solvent was recorded. The increase in the membrane conductivity is partially attributed to condensation of the vapours in the highly microporous membrane even below the saturation vapour pressure and partially to the effect of the polar analyte molecules complexing inside and between the OH groups of the cavities. The technique offers several advantages over existing methods: (i) immunity to water vapour, due to the hydrophobic nature of the membrane; (ii) no catalytic poisoning of the membrane, as is commonly observed for doped SnO₂; (iii) no accumulative effects, which are responsible for baseline drift in quartz-crystal-type sensors, are observed, and (iv) no porous metal layer, the adhesion of which may be prone to degradation, is needed on top of the membrane [54.196].

electronic-nose systems. An electronic nose has been developed to monitor breathing air in human habitats. A molecular modelling study was undertaken to investigate the interactions between resistive sensors of a polymer-carbon black (CB) composite and analytes. Poly(4-vinylphenol), polyethylene oxide, and ethyl cellulose were considered for modelling, based on their stereoisomerism and sequence isomerism. The CB was modelled as uncharged naphthalene rings with no hydrogen. Molecular mechanical and molecular dynamics techniques were employed and the equilibrium composite structure was constructed by inserting naphthalene rings into the polymer matrix. The radial distribution profiles produced information on the composite microstructure. The sensor response was predicted in terms of the interaction energies of the analytes with the composites. Studies included both inorganic and organic analytes [54.198].

Research efforts are also growing in the mineralisation of VOC pollutants to innocuous compounds [54.199]. Visible-light-assisted removal of organic pollutants by photocatalytic action of dye-sensitised TiO₂ surfaces offers several attractive advantages. Firstly, the nanoscale device architecture is versatile with several methods of solar energy conversion whilst producing a chemical fuel in the form

of pure H₂. Secondly pollutant species and concentrations of mixtures in industrial waste streams can be identified [54.200]. Results so far reported are encouraging. For example, 40–75% degradation of aromatic pollutants such as phenol, chlorophenol, trichloroethylene and surfactants was achieved with TiO₂ surfaces modified by methylene blue and rhodamine B dyes af-

ter less than 5 h of irradiation with a 150-W xenon lamp [54.201]. Individual VOCs including methylene chloride, ethanol, benzene, acetone, xylene and isopropanol produced unique signatures as they were oxidised on the sensor surface [54.202]. Interest in hybrid hetero-supramolecular structures will therefore remain alive for the foreseeable future.

Packaging Materials

This chapter is a high-level overview of the materials used in an electronic package including: metals used as conductors in the package, ceramics and glasses used as dielectrics or insulators and polymers used as insulators and, in a composite form, as conductors. There is a need for new materials to meet the ever-changing requirements for high-speed digital and radio-frequency (RF) applications. There are different requirements for digital and RF packages that translate into the need for unique materials for each application. The interconnect and dielectric (insulating) requirements are presented for each application and the relevant materials properties and characteristics are discussed. The fundamental materials characteristics are: dielectric constant, dielectric loss, thermal and electric conductivity, resistivity, moisture absorption, glass-transition temperature, strength, time-dependent deformation (creep), and fracture toughness. The materials characteristics and properties are dependant on how they are processed to form the electronic package so the fundamentals of electronic packaging processes are discussed including wirebonding, solder interconnects, flip-chip interconnects, underfill for flip chip and overmolding. The relevant materials properties are given along with requirements (including environmentally friendly Pb-free packages) that require new materials to be developed to meet future electronics needs for both digital and RF applications.

An electronic package is a configuration of materials that interconnects electronic signals from one area to another. This scheme must isolate these signals so that there is no interference and must also protect the electronics from a degrading environment. A package typically consists

of the semiconductor, mounted and interconnected (with solder or Au wires) to a dielectric substrate (with a lead-frame or with metal traces), which is encapsulated to seal the device from the environment. The electronic package must serve four functions:

- provide electrical (or photonic) contact to and from the chip,
- act as an electrical space transformer to take electronic functionality from the dense surface of the chip to the coarser pitched *outside world*,
- provide environmental isolation to the semiconductor, and
- provide an avenue for conduction of heat away from the device.

In the past, advances in silicon semiconductors had little or no affect on the electronic package design or process. New advances in silicon devices have driven increases in chip speed, device density (e.g., the number of transistors/mm²), and power dissipation. These changes, and those planned in the future, require larger numbers of interconnects to and from the devices, improved electrical performance, more effective thermal management, software systems to design and model the assembly, and different sets of materials to make these changes happen. Furthermore, the package is shrinking to a minimalist version of the products that traditionally have been called packaging. The chip and board

have become a conjugate packaging system that must provide the traditional levels of electrical, mechanical, thermal interfaces, and environmental protection, with the additional challenge of increased performance. Furthermore, the boundary between where the device ends and where the package begins has become blurred with passive devices (e.g., resistors, capacitors, etc.) in the package and redistribution layers that act as space transformers on the chip. Electronic packaging is becoming one of the greatest challenges in manufacturability, performance, and reliability in advanced electronics applications. With the tremendous growth of wireless telecommunication, radio-frequency (RF) applications are beginning to drive many areas of microelectronics traditionally led by the development of the microprocessor. An increasingly dominant factor in RF microelectronics is electronic packaging and the materials needed to create the package, because the package materials strongly affect the performance of the RF electronics. Many challenges also remain for packaging of microprocessors. These challenges include increased speed, numbers of input/output (I/O), decreased pitch, and decreased cost.

55.1 Package Applications

Electronic packages are divided into four levels, three of which exist beyond the integrated circuit.

Level 0: semiconductor chip level (integrated circuits). The materials are the semiconductor (Si, SiGe,

GaAs, etc.), metallization on the circuit (Al, Cu, Au) and interconnects on the die.

Level 1: chip in a carrier. The die is bonded (with a conductive, or nonconductive, adhesive or solder)

Fig. 55.1 Isometric section schematic that illustrates a peripheral package showing a dual-in-line package (DIP) that is wirebonded

Fig. 55.2 Schematic illustration of an area-array package with a flip-chip device interconnect and a ball grid array package

into a package carrier (substrate or leadframe) and interconnected by either wirebonds or bulk conductive interconnects (flip chip) of solder or conductive adhesives. An example of a wirebonded package is shown in Fig. 55.1, while Fig. 55.2 shows a flip-chip package interconnect. The die is protected either by a lid or encapsulated with a polymer overmold.

Level 2: the chip carrier mounted to a board. The package is solder, or conductive adhesive, attached to

a circuit board. An example of a package mounted to a board using area array interconnects is shown in Fig. 55.2.

Level 3: board-to-board interconnects. The boards are interconnected to the final electronic system using friction interconnects, solder interconnects, or fiber-optic connectors.

55.2 The Materials Challenge of Electronic Packaging

Electronic packaging is arguably the most materials-intensive application today. The families of materials included in a package include: semiconductors, ceramics, glasses, composites, polymers, and metals. A list of the types of materials used in an electronic package are shown in Table 55.1. The processes required to assemble a package are equally varied: welding, soldering, curing, cold and hot working, sintering, adhesive bonding, laser drilling, and etching.

Each of these materials and how it is used in an electronic package could be the topic of an entire book. This

chapter is a high-level overview of the materials used in an electronic package. The focus is on the following classes of materials:

Metals are used as conductors in the package, primarily electrical but also thermal for power devices. This includes the thin metal interconnects on the integrated circuit made of Al, Cu or Au and the interconnects between the integrated circuit and the package that are either wirebond interconnects or solder joints. Metals are also used to act as heat sinks for power devices and as shields for RF applications.

Table 55.1 Examples of materials used in electronic packaging

Semiconductors	Si, SiGe, GaAs
Metals	Solders for interconnects (Sn–Pb, Sn–Ag, Sn–Ag–Cu, Sn–Au, Sn–Sb) Au wirebonds Cu leadframes (Kovar, CuBe, Alloy 42) Cu traces in substrates W, Mo traces in co-fired ceramics Ag, Au, Pd for thin/thick films on ceramics Ni diffusion barrier metallizations Al heat sinks
Ceramics	Al ₂ O ₃ substrates modified with BaO, SiO ₂ , CuO, etc. LTCC substrates Al ₂ O ₃ modified with low-temperature glass (e.g., PbO) SiN dielectrics Diamond heatsinks
Polymers	Epoxies (overmold) Filled epoxies (overmold) Silica-filled anhydride resin (underfills) Conductive adhesives (die bonding, interconnects) Laminated epoxy/glass substrates Polyimide dielectric Benzocyclobutene Silicones Photosensitive polymers for photomasks (acrylates, monomers, etc.)
Glasses	SiO ₂ fibers for optoelectronics Silicate glasses for sealing Borosilicate glass substrates Glass fibers for epoxy/glass substrates (FR-4)

Ceramics and glasses are used as dielectrics or insulators. Ceramics are used in devices as dielectrics to form capacitors and inductors. In the package itself, the ceramics are used as insulating materials for substrates that provide a structural base that electrically isolates lines and pads.

Polymers are used as insulators and, in a composite form, as conductors. As an insulator, polymers are encapsulants, underfills and substrates (note: in these applications, polymers are used as composites with silica or glass fillers). Polymers are also used as insulating adhesives to glue components to a substrate or board to provide mechanical strength. The addition of metal particles to the polymer can make it a conductive material as a conductive adhesive interconnect.

Composite materials are a mix of materials that can be tailored for either mechanical behavior improvements or thermal enhancement as an electrical conductor. Many of the composite materials used in packages are based on a polymer matrix, as noted in the polymer section above.

There is a wealth of general information on materials in electronic packaging. Some additional resources are found in [55.1–8].

55.2.1 Materials Issues in High-Speed Digital Packaging

The ability to decrease line width and feature size in semiconductor technology is decreasing below 90 nm. As the feature size shrinks, the function per unit area on the die increases. This increased functionality means either smaller die or more I/O per die. The reduced die size also reduces the available perimeter of the package for wirebond pads while increased functionality requires more I/O. The decreased perimeter area also drives wirebond capability down to 44- μm pitch with 10- μm gold wire. An attractive solution to this decreasing size is to use the entire surface of the chip (flip chip) rather than just the periphery (wirebond). Figure 55.3 shows a comparison of available I/O for a given chip size for standard, and state-of-the-art, wirebond and flip-chip pitch.

From an overall digital package perspective, the trend is to move from perimeter-bonded die and packages, to array packages, then to array die bonds in an array package that offers increased numbers of I/O and performance potential. This trend is shown in Fig. 55.4. Materials used in the package and substrate [e.g., ceramic (Al_2O_3), low-temperature co-fired ceramic (LTCC) and organic laminants] and the package style affect performance as well as area array ver-

Fig. 55.3 Plot of bond pitch requirements as a function of I/O and die size for current wire bond (75 μm) and flip chip (250 μm) and state-of-the-art wirebond (44 μm) and flip chip (150 μm)

sus peripheral interconnects. Ceramic packages are the material of choice for hermetic high-performance applications. Ceramic is typically 96% Al_2O_3 with tungsten metallization. The ceramic is fired and sinters at high temperatures that precludes the use of Cu or Al metallization that would melt in the ceramic sintering process. Multilayer ceramic packages with thin-film metallizations also offer a thermal expansion coefficient similar

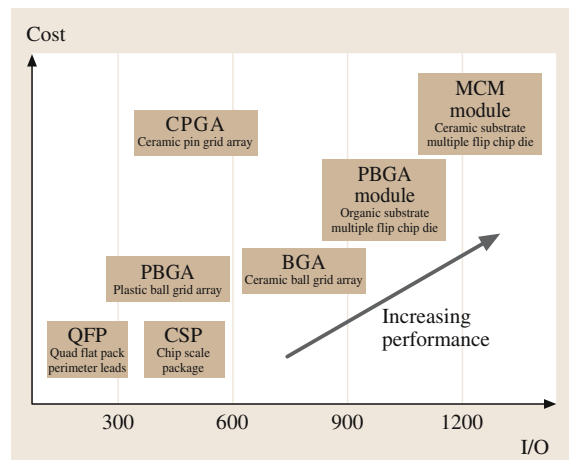

Fig. 55.4 Plot of package style as a function of cost and I/O

Table 55.2 Dielectric constants of packaging substrate materials

Material	Dielectric constant (ϵ_r)
Epoxy	5.0
FR-4	3.5–4.0
Other laminates	2.5–4.5
Kapton	3.1–3.5
Multilayer ceramic	5.0–9.5
Low-temperature co-fired ceramic (LTCC)	3.9–7.8

to the Si die ($6 \times 10^{-6} / ^\circ\text{C}$ for alumina ceramic versus $3 \times 10^{-6} / ^\circ\text{C}$ for Si) so strain that may arise during thermal cycling can be minimized. However, Al_2O_3 ceramic is expensive and has limited use in commercial applications. LTCC is growing in interest because it offers the hermeticity and thermal expansion advantageous of ceramic at a lower cost. LTCC is an alumina ceramic/glass composite that is fired at sufficiently low temperatures that Cu or Ag can be used as the metallization.

For the interconnects in the package, flip chip appears to provide substantial improvements in I/O and pitch but wirebonding will remain as a packaging solution because there is a great deal of capital invested in wirebond equipment that cannot be ignored.

In addition to smaller size driving finer pitch, increased signal speed will drive package requirements. Digital signal delays must be minimized. The total delay is a function of the total distance and the delay per unit length, which is a function of the transmitting medium's dielectric constant and is the square root of the dielectric constant (ϵ_r) times the free-space delay in vacuum (33 ps/cm). Therefore, a material with a high dielectric constant increases the delay. Table 55.2 shows a variety of dielectric constants used in packaging.

For minimal signal delays, an optimal dielectric substrate material is required. The signal length can also be shortened by changing from a wirebond solution to flip chip.

55.2.2 RF Packaging Materials Issues

High-speed and microwave circuits are defined for digital devices with clock speeds faster than 100 MHz and 0.1–100 GHz for analog circuits. For analog, these are also termed radio-frequency (RF) circuits. The microwave, or RF, circuit module is defined by microstrip elements composed of transmission lines and matching networks on a substrate with discrete components (resistors, inductors, capacitors and transistors)

Table 55.3 Coefficients of thermal expansion of a sampling of materials used in area-array electronic packages

Material	CTE ($10^{-6} / ^\circ\text{C}$)

attached, or embedded, in the substrate. A monolithic microwave device has all the above elements integrated onto a semiconductor die. The semiconductor used for RF applications is typically GaAs because of its high resistivity and suitability for circuits that operate at high

frequencies. The following is a discussion of critical packaging materials issue related to RF devices and modules.

One of the most significant differences between RF and digital packaging is that the package is part of the RF circuit due to the interaction of the RF electric field with all adjacent conductors and insulators. This is one of the most significant challenges in the design of RF circuits. This will be further exacerbated as the trend moves from single-die RF packages to multiple die with passive components in RF modules. For example, the wireless-communication industry is striving toward a solution of a

phone in a package where the entire electronic functionality of a cellular phone can fit into a package with a size on the order of 1 cm^2 . Materials used in the package of these RF applications are significant for the performance and cost of the solution.

It is clear that the electronic package is a complex materials system that is driven by a variety of thermal, mechanical and electrical performance requirements. These requirements are also application dependent for both digital and RF packages. The remainder of this chapter is an overview of the key materials required for microelectronic packaging.

55.3 Materials Coefficient of Thermal Expansion

The coefficient of thermal expansion (CTE) is the length of increase of a macroscopic sample for a given temperature increase. The units of the CTE are length/length $^{\circ}\text{C}$. The CTE is a critical physical property of materials used in an area array package. A wide variety of materials with a wide variety of CTEs, such as metals, ceramics, and polymers are joined together

in an electronic package assembly. As processing (or in-use) temperatures change, the materials expand or contract to various degrees that could result in the formation of extensive and nonuniform strains in the package assembly. A set of materials typically used in electronic packages and their CTEs are shown in Table 55.3.

55.4 Wirebond Materials

Wirebonding is the process where a thin wire (that can be less than $25\text{ }\mu\text{m}$ in diameter) made of Au or Al is bonded to the surface of an integrated circuit, then to a pad or leadframe in the package (Fig. 55.1). Gold-ball thermosonic bonding is the typical method used to form these interconnects. The thermocompression bond is a weld between two metals where thermal energy (preheating of the capillary tool and wire), force and ultrasonic energy are imparted to the wire, causing it to melt on the surface and rapidly interdiffuse with the bond pad to form a joint. The integrated circuit pad's surface finish is typically Al or Au and the package bond pad finish is typically Au or Cu.

55.4.1 Wirebonds for Digital Applications

The challenges for decreased wirebond pitch are primarily process related to accurate machine control to move bonding heads to shorter distances ($44\text{-}\mu\text{m}$ pitch) with increased accuracy. However, there are also materials challenges. The metallurgical challenges of wirebonding Au to Al have been well addressed. The classic, early failures were dominated by *purple plague* and the definitive work in this area is by *Philofsky* [55.9]. Purple

plague resulted when the Au of the wirebond extensively reacting with Al to form brittle AuAl_2 that resulted in bond failures. (Purple plague derives its name from the purple tinge of the AuAl_2 intermetallic.) This was addressed by reducing the wirebond process temperature to below 300°C , which reduces the extent of AuAl_2 formation. Current wirebond failures are the result of surface impurities or corrosion. These are addressed by plasma or ultraviolet (UV)–ozone cleaning of the surface prior to wirebonding.

Wirebonding problems have also been caused by plating impurities in Au bond pads. Impurities in the Au diffuse to the molten front that occurs during wirebonding and concentrate in a plane in the bond. If there are a sufficient number of impurities, they precipitate and act as sinks for vacancies that can become voids and lower the bond strength. The impurities have been identified as Ni, Fe, Co and B [55.10]. The contaminants are present in the Au film as a result of the plating process. This can be addressed by optimizing the plating process to form pure metallic Au.

With finer-pitch wirebonding comes the requirement for thinner Au wire, approaching $10\text{ }\mu\text{m}$ in diameter. This thin wire poses a materials challenge. The wire

Fig. 55.5 Schematic illustration of the grain size in a Au wirebond. (After [55.11])

must have sufficient ductility to deform to the required wirebond shape but retain sufficient strength not to deform or move during the molding process (wire sweep). The Au alloy must be optimized for these opposing requirements. Au wire is typically stabilized with Cu and Ag dopants at levels below 100 ppm by weight. These dopants keep the grain size small to retain strength without deleteriously affecting ductility. As the Au wire decreases in width, the levels of dopants may need to be increased, reducing the Au to less than the current 99.9% level. Proposed dopants include Be and Cu. The critical region in the wirebond is above the ball and be-

low the wire, known as the heat-affected zone (HAZ). A schematic of the zone is shown in Fig. 55.5. This zone forms above the ball that was melted and cools to form a very large as-solidified grain size. The HAZ forms a large grain size while coarsening in the solid state as the molten ball is created. [The ball is formed under a flame or high current, solidifies, and is then placed on a Au or Al pad and with the addition of energy (pressure/heat/vibration) forms a solid-state ball bond.] The strength in the HAZ is reduced by the Hall-Petch relationship that states that strength is inversely proportional to grain size. The HAZ would be susceptible to potentially high levels of strain during molding and would be the most likely failure location. In thinner wires, an increased grain size is even more critical and alloying elements are needed to stabilize the structure and retain sufficient strength without affecting the ductility required to form the wirebond.

55.4.2 Wirebonds for RF

At RF frequencies, wirebonds affect electrical performance. At sub-RF frequencies, the wirebonds can be neglected as their resistance and inductance are in the noise with respect to performance. In RF applications, the wirebonds experience parasitic losses due to inductance with adjacent wirebonds, resulting in signal disturbance. RF-circuit designers typically add at least 1-nH inductance per wirebond but the effect can be variable and must be physically compensated by tuning the circuit. In effect, the wirebonds act as discrete inductors. The materials issues for RF wirebonds are the same as those described above for digital circuits but the effect of the wirebonds themselves is more significant in RF compared to digital and must be accounted for in the design of the device.

55.5 Solder Interconnects

For surface-mount and area array applications, the role of solder in the package is significant. In these advanced designs, the solder is an electrical interconnect, a mechanical bond and must often serve as a thermal conduit to remove heat from the joined device. The interconnects become more critical as chip size, chip carrier size, and the number of I/Os increase, while the solder joint size and cost decreases. Furthermore, some of the use environments are becoming increasingly severe. For example, some automotive electronics are being

placed in locations under the hood with temperature extremes that could range from -55 – 180°C . Portable devices, such as cellular telephones are expected to withstand severe shock environments caused by dropping a phone.

A solder interconnect consists of the solder alloy and the pads to which it is joined. The solder alloy is a low-temperature-melting metal that wets and reacts with metal pads or leads to form a metallurgical bond. During the wetting process the solder reacts with the

Fig. 55.6 Optical micrograph of the near-eutectic 63Sn–37Pb solder microstructure with the lamellar Sn- and Pb-rich phases and dendrites indicated

pad metallization, forming an intermetallic compound (IC) on the pad surface that continues to grow when the solder is in the solid state.

The most commonly used solder alloy for electronic interconnects is near-eutectic Sn–Pb with a composition of 63Sn–37Pb (by *wt%*). The microstructure of this alloy is shown in the optical micrograph in Fig. 55.6 and consists of Sn- and Pb-rich lamella. The lamella are oriented as cells after solidification with the slightly coarsened regions that separate the individual cells as the last part of the solder to solidify. This alloy melts at 183 °C. Pb-rich Sn–Pb alloys (such as 95Pb–5Sn or

97.5Pb–2.5Sn) are used for soldering temperature hierarchies as these alloys melt at temperatures in excess of 300 °C. The microstructure of Pb-rich alloys consists of a matrix of large Pb grains decorated with Sn precipitates. In flip-chip applications die are soldered to substrates with high-Pb solder. The substrates are soldered to a board with near-eutectic Sn–Pb. The Sn is the active components of these solder alloys and reacts with metallizations such as Cu or Ni to form intermetallic compounds.

Other solder alloys have found some use in electronic packaging, including Sn–Ag, Pb–In, Sn–Sb, etc. These alloys are used for a variety of applications including creating a soldering temperature hierarchy (higher or lower than Sn–Pb) or slowing the reaction rate with the metallization (e.g., In), or changing the mechanical properties of the joint. These alloys either form as a single-phase matrix with precipitates or as two-phase structures similar to eutectic Sn–Pb. The focus of this section, however, is on the most commonly used solder alloy, eutectic Sn–Pb.

The microstructure of the solder influences the mechanical behavior and reliability of the interconnects by governing the deformation and failure process. Typical deformation depends on the motion of dislocations and the growth and reconfiguration of grains and this is more sensitive to the structure of the solder than its chemistry. Therefore, depending upon processing conditions, the same solder alloy can respond differently to imposed stress and strain. Additionally, solders

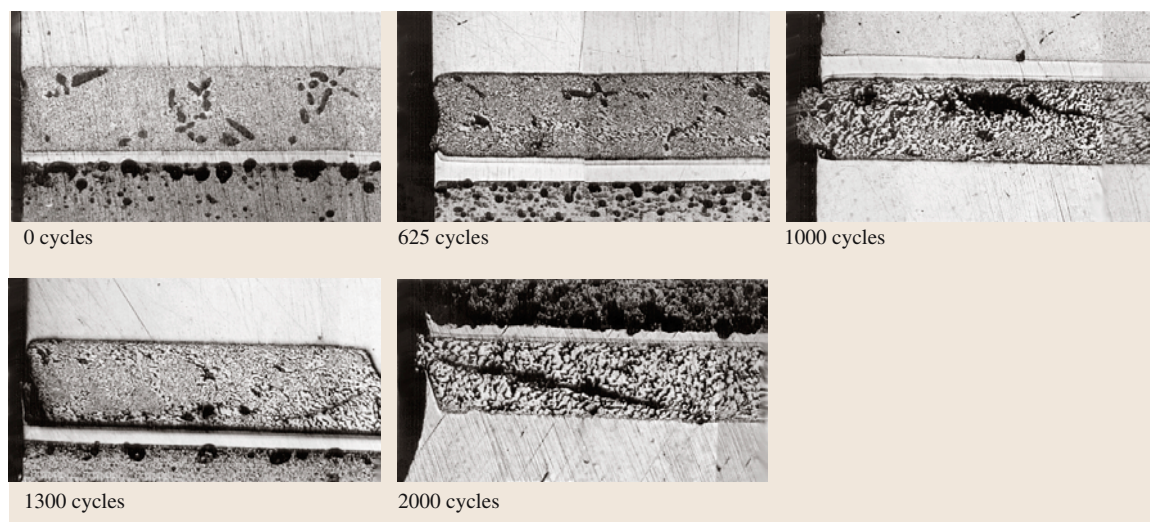

Fig. 55.7 Optical micrographs that show heterogeneous coarsening of the eutectic Sn–Pb microstructure at colony boundaries after thermomechanical fatigue

are low-melting-temperature materials that are used at a significant fraction of their melting point and are thermodynamically unstable. As the joint ages (at temperature and under strain) the microstructure changes and the mechanical properties and reliability change. The microstructure changes by grain (or phase) coarsening, which may be heterogeneous or homogeneous. Furthermore, the interfacial intermetallic grows in thickness and coarsens with time at temperature. All of this must be comprehended to determine the reliability of solder interconnects.

Thermomechanical fatigue occurs when materials with different CTEs are joined and used in an environment that experiences cyclic temperature fluctuations resulting in imposed cycling strain. Thermomechanical fatigue is a major deformation mechanism affecting solder interconnects in electronic packages. Even small temperature fluctuations can have a large effect, depending upon the joint thickness and CTE difference of the joined materials. The strain imposed on the solder joints follows the relation:

$$\Delta\gamma = \Delta\alpha\Delta Ta/h,$$

where $\Delta\gamma$ is the shear strain imposed, $\Delta\alpha$ is the difference in coefficient of expansion between the joined materials, ΔT is the temperature change, a is the distance from the neutral expansion point of the joined materials, and h is the thickness of the interconnect. After a critical number of thermal excursions, such as machine on/off cycles, solder joints experience fatigue failure. The type and magnitude of strains in solder joints under conditions of thermomechanical fatigue are often quite complex. For surface-mount applications, the strain is nominally shear. However, tensile and mixed-mode strains can occur due to bending of the chip carrier or board.

The combination of strain and temperature during thermomechanical fatigue has a large effect on the microstructure, and microstructural evolution of eutectic Sn–Pb solder joints. The microstructural evolution of 60Sn–40Pb solder as a function of the number of thermal cycles (-55 – 125°C) is shown in Fig. 55.7. The microstructure evolves through deformation that concentrates at the colony boundaries closely parallel to the direction of imposed shear strain, causing the cells to slide or rotate relative to one another. The structure within the cell boundaries becomes slightly coarsened relative to the remaining solder-joint microstructure and, thus are the weak links of the joint. Damage (in the form of defects or dislocations) is created at the cell boundaries at the low-temperature portion of a thermal

cycle. As the temperature rises, the deformation is annealed by recrystallization or stress-assisted diffusion, where material diffuses to regions of high stress. This results in coarsening of the Sn-rich and Pb-rich grains and phases in colony boundaries. The heterogeneously coarsened colony boundaries are weaker than the rest of the joint and any further deformation concentrates in the coarsened regions, resulting in further coarsening. Failure eventually occurs due to cracks that form in the coarsened regions of a joint. The first indications of impending failure are associated with cracking of coarsened Sn-rich grains in the heterogeneous region whose initial as-solidified grain size is in the submicron range. When cracks initiate during thermomechanical fatigue, the Sn-grains have grown to 5 – $10\text{ }\mu\text{m}$. Failure occurs when grains can no longer slide and rotate to accommodate the imposed strain, resulting in intergranular separation.

Lead-rich Pb–Sn alloys undergo thermomechanical fatigue behavior but show little evidence of microstructural evolution. These solders undergo intergranular failure caused by void coalescence and growth at Pb grain boundaries. The strain imposed during thermomechanical fatigue cannot be accommodated by large Pb grains, resulting in intergranular failure. However, Pb loses the work-hardening effect quickly so that damage in the form of cracks does not propagate easily.

Other solder alloys, such as the Pb-free Sn–3.5Ag eutectic-based solders, experience thermomechanical fatigue damage and failure at Sn grain boundaries. The microstructural evolution in these alloys tends to be phase coarsening with minimal grain-size coarsening. Sn–Ag–X alloys tend to have longer thermomechanical fatigue lifetimes than near-eutectic Sn–Pb solders.

Intermetallic compounds form between pad metallization and the active components of the molten solder (typically Sn). For Cu metallization, the Sn reacts to form Cu_3Sn and Cu_6Sn_5 intermetallics. For Ni, the Sn reacts to form Ni_3Sn_4 . After solidification, the intermetallic compounds continue to grow by solid-state diffusion. Over long periods of time, the intermetallic layers can grow to significant thicknesses ($> 20\text{ }\mu\text{m}$) and the solder–intermetallic interface may contain easy sites for crack initiation and propagation. Excessive growth also consumes the base metal, or finish, that can result in the loss of adhesion to the underlying metal that is not solder-wettable or create a plane of weakness owing to the stress generated from an intermetallic layer that is too thick. The metallized pad thickness must generally be greater than that consumed by the solder.

The transformation of solder-wettable coatings into intermetallics by solid-state reactions can also result in excessive intermetallic growth that degrades mechanical properties. The interfacial intermetallics are brittle and may fracture when strain is imposed, especially if the strain is tensile in nature. Solder-joint interfacial intermetallics are brittle because they typically have complex crystal structures with few crystallographic planes available to accommodate stress by strain relief, i. e., plastic deformation via a slip mechanism. The failures are characteristically brittle and occur through the intermetallic or at the intermetallic/solder interface under low-load conditions.

55.5.1 Flip-Chip Interconnects

Recent developments in under-bump metallurgy (UBM) and solder joints have resulted in lower cost and higher performance flip-chip interconnects. The UBM serves as an electrical, thermal, and mechanical interface between the silicon bond pads and the package substrate. The structure of the UBM is designed to adhere to the Al on the Si, act as a diffusion barrier between the solder and Si, and be a wettable surface to join to the solder. The most common UBM is the evaporated Cr/Cr-Cu/Cu/Au developed by IBM [55.12] for use with an evaporated high-Pb-content Pb-Sn alloy joined to a ceramic substrate. This UBM is expensive and new UBM systems with sputtered or plated metallizations have been developed. Plated metallizations are the lowest cost UBMs.

A significant change in flip-chip interconnects is the move toward a lower-melting-point solder alloy, such as eutectic 63Sn-37Pb (*wt%*) that can be processed below 220 °C as opposed to 350 °C for high-Pb solder. New materials on the die (low-*k* dielectric) and substrate (organic materials) require this lower processing temperature. The change in solder alloy also requires a change in the UBM. Traditional UBM systems are based on a thin Cu layer that dissolves into high-Sn solders, resulting in spalling and dewetting. Eutectic-solder UBM systems utilize a layer of Ni for solder wetting. The Ni is wet by Sn-Pb solder but reacts much more slowly than Cu. The addition of $\approx 9\%$ V to Ni reduces the ferromagnetic behavior of the Ni and enables the use of sputtering of the Ni. Electroless plating of Ni-9%P is the lowest-cost UBM and has the advantage that plating occurs only where desired on the metal pads on the silicon. To plate onto Al, the pads are zincated, then immediately plated with Ni. One issue with Ni-based UBMs is the intermetallic layer between the solder and

Ni (Ni_3Sn_4). Although very thin, this intermetallic layer can be brittle and the long-term reliability must be fully characterized and understood.

There are three solder deposition techniques available for flip chip. Traditionally, high-Pb solder is evaporated onto the UBM then reflowed to form metallurgical bonds. Evaporation is expensive because the masks must be regularly cleaned and there is excessive scrap solder. The composition of evaporated solder is difficult to control outside the high-Pb regime. Solder paste is a lower-cost alternative to evaporation and involves screening the paste onto the UBM then reflowing. Solder paste reduces waste, cleaning is inexpensive, and the paste comes in a variety of compositions, including eutectic Sn-Pb. The difficulty with paste arises in fine-pitch applications where the rheology of the paste makes it difficult to force into the required small holes in the screen. Solder may also be plated, which is inexpensive (no waste and easy cleaning) and has excellent fine-pitch coverage. Solder bumps at a pitch of 25 μm have been achieved by plating. The difficulty with plating is achieving ball and compositional uniformity.

The trend in flip-chip interconnect pitch is that the current 250- μm pitch will continue to shrink. The driving force for this pitch shrink is to satisfy the requirements for high-performance silicon devices. These requirements include a dramatic increase in the number of I/O due to increases in the number of signal lines and power requirements. Higher-power devices require more signal and ground lines and, to limit point sources of heat the power and ground interconnects should be spread evenly across the area array.

There are a number of materials and processing challenges associated with finer pitches. As the pitch shrinks, the methods to deposit the solder become more limited. Solder paste is very difficult to deposit using a silk-screen method at pitches below 150 μm due to rheological limitations of forcing a semi-solid (the paste) into small holes (the silk screen). Evaporation is difficult because developing a metal screen mask with the required tolerances is prohibitively expensive. Solder plating is still a good option but the solder must be very uniform across each die. Solder ball uniformity is critical because large variations between die could result in electrical opens, for small balls, and shorts, for large balls. At 250 μm , ball uniformity across a die is 10%, at 150 μm this decreases to 5% and the change in dimension tolerance is 12.5 μm down to 3.75 μm . An additional issue with a decrease in ball size is that the joint gap between the substrate and the die decreases to the point that it may

become very difficult to flow underfill completely under the die. At 100- μm pitch the gap between the die and substrate could be significantly less than 25 μm , below the limit of underfill flow. For these very-fine-pitch applications an alternative underfill technique will need to be developed because flow under the chip will not be possible. One alternative would be to deposit the underfill material on the wafer immediately after flip-chip solder bumping then underfill cure would simultaneously occur during solder reflow. New underfill materials and processes must be developed to implement this process.

55.5.2 Flip Chip for RF

Flip chip provides substantial improvements in off-circuit **RF** performance because the inductance is decreased as the ball height and shape is very consistent and predictable. Wirebond lengths can vary (typically $\pm 100 \mu\text{m}$), resulting in parasitic variations not observed in flip-chip interconnects. The number of I/O on an **RF** circuit is generally small so the pitch of the interconnects is generally quite large.

The die interconnects on GaAs are typically Au whereas on Si they are Al. A UBM is required for Si applications because solder does not wet Al. The solder would wet the Au of the GaAs but the Au layer is very thin and would dissolve the entire Au layer very quickly so a UBM is also required for GaAs. The UBMs available for Si can also be applied to GaAs but can be simpler because the adhesion of other metals to Au is easier to achieve than it is on Al.

The solder alloys for GaAs flip-chip bumps tend to be similar to that for Si but with a greater emphasis on Au-based alloys because of the desire to use a highly conductive material such as Au for very-high-speed applications. Eutectic Au–Sn, Ag and In alloys have been commonly used but the wetting of these solders is typically poor. For finer-pitch applications on GaAs (due to the small die size, not large numbers of I/O) other materials with good wetting are needed. Conductive adhesives have been explored for GaAs bumps. Work by Lin et al. [55.13] found no significant difference in electrical performance up to 2 GHz between a conductive adhesive and Au–Sn solder. The use of underfill for flip-chip packages can cause a major loss in **RF** energy because the high dielectric constant of the underfill polymer is greater than that of air. With a conductive adhesive localized to just the bond pads, not the entire surface of the die, this **RF** loss will not be observed.

55.5.3 Pb-Free

The electronics industry extensively uses Pb–Sn solder alloys in flip-chip applications as well as in many other interconnects in the electronic package. However, medical studies have shown that Pb is a heavy-metal toxin that can damage the kidneys, liver, blood, and central nervous system. Less than one percent per year of global Pb consumption is used in solder alloys for electronic products but electronics and electrical systems make up an increasingly larger fraction of landfills [55.14]. The issue of Pb leaching from landfills into the water table has raised alarm as a potential source of long-term contamination of soil and ground water. Concerns about the presence of Pb in the environment and potential exposure scenarios that could result in the ingestion of Pb by humans and wildlife have prompted a concerted effort to limit the use of Pb in manufactured products (notably gasoline, plumbing solders, and paint). International laws have recently been proposed to expand Pb control laws to limit or ban the use of Pb in manufactured electronics products. The most aggressive and well known effort is the European Union's Waste in Electrical and Electronic Equipment (WEEE) directive that proposes a ban on Pb in electronics by 2006. The Japanese Environmental Agency has proposed that Pb-containing scrap must be disposed of in sealed landfills to prevent Pb leaching. Electronics manufacturers have responded to these proposed bans in a variety of ways. Many companies have not taken a stance, hoping that legislation will not be enacted. Other companies have aggressively pursued solutions to the proposed bans and are using Pb-free products as a *green* marketing strategy. Extensive research on Pb-free solders has been published. A comprehensive review of the status of Pb-free solders, primarily focused on carrier-to-board (surface-mount and through-hole) interconnects, can be found in the literature [55.15–19]. A growing requirement is Pb-free solders for flip-chip interconnects.

One benefit of a Pb-free flip-chip interconnect is the reduction of Pb^{210} -created alpha-particle radiation. All mined Pb contains a small amount of radioactive Pb^{210} that decays and emits alpha particles. When an alpha particle enters an active element of the Si (such as a memory cell) it has sufficient energy to cause the stored charge to be released with the result of changing stored memory from a 1 to a 0 state. There is no permanent damage to the Si itself so this radiation-induced fault is termed a *soft error*. The alpha particles have a low energy that is dissipated over relatively short distances. However, due to their proximity to active

elements, the flip-chip solder interconnects have sufficient levels of alpha-particle radiation to induce soft errors in complementary metal–oxide–semiconductor (CMOS) technology, which become more critical as the cell size on the die is reduced [55.20, 21]. For Pb–Sn solders, one solution to alpha-particle radiation is to use elemental Pb that was mined many, many years ago where the majority of Pb^{210} has decayed. The source of this Pb is typically found as the ballast of shipping vessels that sank almost 2000 years ago and is relatively expensive. The elemental constituents of Pb-free solders (Sn, Cu, Ag, Bi, In, Sb), however, do not radioactively decompose so alpha-particle radiation is minimal.

Flip-chip interconnects are the electrical and mechanical connections between the semiconductor integrated circuit and the package [or board for direct chip attach (DCA)]. These interconnects are formed on the periphery or in an area array on the top surface of an active die. Flip-chip interconnects are formed by depositing solder onto a metallized Si wafer in the form of discrete balls, solder paste or by directly plating onto the pads on the wafer. The solder must wet and join to the pads on the Si devices so an under-bump metallurgy (UBM) is typically deposited on the Al or Cu pads on the Si. The UBM typically consists of a barrier metal (e.g., Ti or W) followed by a solder-wettable layer (e.g., Cu or Ni). The top layer of the Ni metallization is covered with a noble metal, such as Au, to prevent oxidation that

would inhibit solder wetting. The UBM also acts as a diffusion barrier between the Si and the solder and must be thick enough to withstand interactions (intermetallic formation) between the solder and UBM. Flip-chip interconnects are smaller (on the order of 100 μm in diameter) than surface-mount joints and are projected to have pitches that will shrink below 150 μm . Flip-chip interconnects have a unique set of requirements. These joints must be able to withstand a potentially high level of strain mismatch between Si and an organic substrate. Flip-chip technology has moved from ceramic packaging with high-Pb solder (97.5Pb–2.5Sn) to an organic package that requires lower-temperature reflow ($< 260^\circ\text{C}$). This can be accomplished by bumping the die with high-Pb solder then joining it to an organic board with eutectic Sn–Pb but this is a cost increase that is eliminated with a monolithic solder. The joints must withstand board-level reflow environments compatible with joining to organic substrates that, again, have a maximum reflow temperature of 260°C . The Pb-free solder must meet these requirements and perform at, or above, the level of performance of the Sn–Pb solder it is intended to replace. The flip-chip solder alloy is typically deposited on Si wafers either as solder paste stencil-printed on the defined UBM pads or by direct plating on the UBMs. The simplicity and low cost of plating the solder for flip-chip interconnects makes electrochemical deposition the most attractive choice for flip-chip bumping.

55.6 Substrates

The move to organic substrates is the focus of extensive development effort worldwide by both printed circuit board manufacturers and traditional suppliers that requires significant amounts of capital. Cost savings are expected by replacing ceramic substrates with organic substrates. One stated reason for moving to an organic substrate is based on the belief that, in volume production, organic materials are less expensive than ceramics due to the nature of printed circuit board processing. The organic substrate also offers an increase in electrical performance due to its lower dielectric constant (therefore, less capacitance and better speed) of 3.5 for organic versus 5.0 for ceramics.

Advanced substrates for flip chip must also provide increased wireability while delivering improved electrical performance with reliability levels at least equivalent to current surface-mount applications. The

board interconnect density for flip-chip substrates must accommodate the increasing density of off-chip interconnect, and cost-effective substrate capability that combines the necessary fine-line and micro-via features must be developed. Micro-vias are the metal-filled holes that provide a conduction path between copper lines in the multiple layers of an organic substrate. Micro-via capability must also scale with line width/spacing in order to provide the *via in line* structures which will be necessary to support bump pitch densification. At a pitch of 250 μm , micro-vias can be created using a photolithographic process. At finer pitch, laser drilling techniques are used to create the required small via size to support the smaller capture pads and facilitate the dense routing required for flip chip.

Materials with dielectric constants approaching 2.0 with coefficients of thermal expansion approach-

Fig. 55.8 Schematic illustration of RF electric-field lines in the microstrip and coplanar designs

ing 6.0 ppm/°C are necessary to meet fine pitch requirements. Furthermore, uniformity and flatness requirements must be improved on organic substrates to ensure uniform joint size and bonding across each die as the interconnect pitch decreases.

The change in substrate materials drives the need for a lower-melting-temperature solder to replace the high-Pb-content Sn–Pb alloys that are processed in excess of 300°C for ceramic substrates. The organic materials in a substrate are typically epoxy-based and char or burn at temperatures in excess of 250°C. The most common solder alloy candidate is near-eutectic Sn–Pb, which can be processed well below 250°C ($T_{mp} = 183^\circ\text{C}$). However, this could result in a situation where the flip-chip interconnect melts every time a subsequent solder reflow occurs. Multiple reflows of the solder interconnects accelerates intermetallic growth between the tin of the solder and the metallized pads for the UBM and substrate. One way to circumvent this issue is to deposit low-melting-temperature eutectic Sn–Pb solder on the substrate lands, or on the high-melting-temperature solder bump. Reflow to the substrate can be performed at eutectic Sn–Pb soldering temperatures but the mixing between the high-Pb-content and eutectic solder results in a higher-melting-temperature composition. Subsequent reflows, at eutectic Sn–Pb processing temperatures, will not remelt the *composite-alloy* flip-chip joint. This addresses the low-temperature processing requirements for organic substrates but does not address the low- κ -dielectric

low-temperature processing requirements because the high-Pb-content solder must still be reflowed on the silicon.

55.6.1 RF Substrate Materials

Optimum electrical performance is achieved in an RF module when the signal-carrying conductor is adjacent to the ground plane to contain the electric field. In microstrip designs the conductor is above the ground plane, in coplanar designs the conductor is sandwiched between ground planes, as shown schematically in Fig. 55.8. These designs affect the materials in the package. The impedance of the lines is desired to be 50 Ω (which matches the radiation impedance of the antenna to air). The impedance is affected by the conductor material, typically Au, and the dielectric material [Si, SiGe, GaAs, for the die and LTCC, Al_2O_3 or epoxy (organic) for the substrate].

Like its digital counterpart, RF packaging is moving away from the Al_2O_3 ceramic substrates used in RF applications to the lower-cost solution of LTCC and organic materials. The metallizations used are Cu on the interior of the substrates and Au as the top-layer metallization to improve RF performance.

Organic substrates offer a lower-cost solution. This substrate is built in a laminate structure with punched, or laser-drilled, holes that are subsequently plated for interlayer via interconnects. The laminant layers are variations of epoxy and glass optimized for low dielectric constants. LTCC substrates are also laminant structures of sheets of LTCC with laser-drilled and plated vias. Recently, LTCC materials have been optimized to not shrink in the x – y plane during the sintering process (z -direction shrinkage, however, is significant). The LTCC laminants are extremely thin, compared to organic, and offer the opportunity to build complex RF substrates.

An additional trend in RF substrate technology is to move the discrete functions of RF module circuits from surface-mounted components to embedding them in the substrate. These embedded functions are typically capacitors and inductors and occasionally resistors. This can be done because the substrate material is dielectric and metal, which are the basic components of passive devices. The advantages of embedding components are reduced size, reduced cost and improved performance. Size can be reduced because surface-mount components take up a great deal of the surface of the substrate. By embedding these components, they are thinner and the area is reduced. Cost is reduced because the embedded

passives are formed as part of the laminant layers by patterning the metal/dielectric and is essentially cost-free because the patterning would be done regardless. Performance can be increased through the smaller size of the module. The embedding of components in substrates does offer the opportunity for improved materials. Per-

formance could be improved by finding means to alter the materials properties of regions of the laminant layers to optimize the electrical performance of discrete components that are to be embedded (i. e., *seed* regions of the substrate for optimal capacitance, inductance and resistance).

55.7 Underfill and Encapsulants

55.7.1 Underfill

Flip-chip technology demands that the space between the chip and the substrate be filled with a dielectric organic material to help mechanically interlock the chip to the substrate. Most underfill materials available are silica-filled anhydride resin polymers. The filler provides the strength in the composite polymer and the resin bonds with the die and substrate. Without the underfill the difference in coefficient of thermal expansion between the chip ($3 \text{ ppm}/^\circ\text{C}$) and the substrate ($\approx 17 \text{ ppm}/^\circ\text{C}$) would quickly result in fracture of the solder interconnects when variations in temperature occurred. New underfills must be developed to accommodate increased bump density and shrinking of bump height. As bump density increases and pitch decreases, the underfill must flow into smaller spaces. A $250\text{-}\mu\text{m}$ pitch requires an underfill with a thickness of $110\text{-}\mu\text{m}$. At a $150\text{-}\mu\text{m}$ pitch, the dimension between the chip and substrate will be less than $50\text{-}\mu\text{m}$ but 100% fill of underfill is still required. Traditional flow dispensing and curing may not be suitable in these thin spaces due to a lack of capillary driving force (current underfill materials flow through a minimum thickness of $75\text{-}\mu\text{m}$). For very thin fill spaces, wafer-level deposition of the

underfill needs to be developed. This wafer-level deposition involves spinning on of an uncured polymer to a uniform thickness slightly less than the bump height. The wafer would then be diced and die-mounted on substrates. Reflow would form the solder joints and cure the underfill, simultaneously. The filled polymer must be spun to a uniform thickness of $25\text{-}\mu\text{m}$ or less, and bond well with silicon and substrate materials, and also be compliant.

55.7.2 Encapsulation

Encapsulation of electronic packages is required to protect the electronic components from environmental degradation such as moisture contamination, mechanical damage and must also provide electrical isolation. The encapsulation material is a polymer that flows over and covers the electronic components, and then cures into a solid. For electronic packaging, the most common method for applying the encapsulation is transfer molding. Figure 55.9 is a schematic illustration of the transfer mold process. The transfer mold compound material is typically a thermoset cross-linking polymer. The polymer resin portion forms 25–35% of the total mold compound (by weight) and consists of epoxy resin, a hardener and a curing agent. The mold compound material is filled with powders of silica (SiO_2), alumina (Al_2O_3) or glass (65–75% of the total weight) to reduce the thermal expansion coefficient of the polymer and add strength. Amorphous silica is used for minimum thermal expansion coefficient but this results in a decrease in thermal conductivity. Crystalline silica improves thermal conductivity but is abrasive to the molds themselves. Small amounts of pigments (to color the mold compound), accelerants, flame retardants, mold-release agents, getterers, and antioxidants are also added to the final mold compound. Pellets of the mold compound are placed into a heated cavity at the top of the mold and pressure is applied by a ram that pushes the liquefying materials into the mold. The material

Fig. 55.9 Schematic illustration of the transfer mold process

is forced through channels and through a constriction (called the gate) that provides back-pressure and regulates the flow rate of the molten mold compound. After passing through the gate, the mold material flows across the component being encapsulated. The heat is turned off and upon cooling the polymer cross-links, with the use of a curing agent (typically an amine) that is included in the mold compound. The mold compound material has good adhesion, good stability with regards to temperature, chemicals, and the environment. It also cures rapidly, has low permeability to moisture and high dielectric strength.

The transfer mold process has the advantage that part dimensions are very well controlled. The process and materials are low cost and high-volume manufacturing is possible.

An issue with the mold compound encapsulation processing is wire sweep, where the force of the viscous encapsulant can push bond wires to short with one another. This has been addressed with optimized filler size and shape and mold temperature and pressure. After molding, the difference in thermal expansion between the cured mold compound and the rest of the package (the substrate, leadframe, semiconductor device, etc.) can result in considerable stresses at the interfaces. Furthermore, the CTE of mold compounds changes when the material goes above the glass-transition temperature, T_g . T_g is the temperature at which the polymer changes from a rigid structure to a softer, more glass-

like structure. Below T_g , the CTE of typical mold compounds is $20 \times 10^{-6} / ^\circ\text{C}$ but above T_g this can increase to $60\text{--}70 \times 10^{-6} / ^\circ\text{C}$. The T_g of mold compounds varies but is usually $175\text{--}200^\circ\text{C}$ below the solder processing temperatures, which are typically in excess of 220°C . After cooling from mold processing, the mold compound forms a compression seal with the materials that expand less (leadframe, substrate, semiconductor). However, upon heating to solder process temperatures, the stress is reversed to tensile and can result in interfacial cracking, or delamination. The interfacial cracks provide a conduit for the ingress of water or ionic contaminants that could result in corrosion of metals in the package (particularly Al bond pads). This issue must be addressed by optimizing the mold compound to the package application (materials and size) to minimize strain and to maximize interlocking mechanisms between the mold compound and the substrate/leadframe.

Mold compound encapsulation is generally detrimental to RF device performance. The encapsulant materials are nonuniform and degrade performance because the electric field generated by the RF circuit in the encapsulant is nonuniform, resulting in lossy behavior. Many high-performance RF packages are designed with a cavity and are made out of ceramic with a metal lid to form the cavity. However, plastic encapsulation is required to achieve the required low-cost reliability of the package, so a trade-off must be made for performance, reliability and cost.

55.8 Electrically Conductive Adhesives (ECAs)

Electrically conductive adhesives (ECAs) are composite materials consisting of a dielectric curable polymer and metallic conductive particles. ECAs are low-temperature alternatives to solder alloys. The polymer is an adhesive material that reacts chemically with metals to form a bond. The metallic particles in the adhesive form a network in the cured joint that forms a conduction path in area-array applications.

55.8.1 Adhesive Polymers

The polymer portion of the adhesive is available in two forms: thermoplastic and thermosetting. A schematic illustration of these two types of polymers is shown in Fig. 55.10. A thermoplastic polymer is a linear chain of linked monomers (nominally, hydrogen-carbon bonds). After curing, thermoplastic polymers becomes

more rigid, but remain flexible. As the temperature is increased, these polymers essentially become molten. This provides a method to repair or replace components with thermoplastic joint area-array joints. Thermosetting materials are similar to thermoplastics, except that monomer chains become cross-linked in three dimensions during the curing stage. The number of cross-links determines the rigidity and the glass-transition temperature (T_g) of a thermoset polymer. In general, the more cross-links, the higher the T_g . A curing agent (e.g., a hardener) can be added to thermoplastic polymers to cause the cross-linking reaction in these materials as well. Curing can be performed using UV light, heat, or catalysts. Thermosetting materials are harder than thermoplastics, but can be processed and cured below their T_g and do not become molten above the T_g . However, the curing operation is not reversible, mak-

Fig. 55.10 Schematic illustration of polymer bonds for thermoplastic (linear bonds) and thermosetting (cross-linked bonds) electrically conductive adhesives

ing repair difficult. Examples of thermosetting materials include epoxies and acrylics. ECAs are typically made using either thermosetting or thermoplastic polymers, or a combination of the two.

55.8.2 Metal Fillers

A number of metals have been used to provide the electrical conductivity of ECAs. The metals are typically in the form of flakes, plates, rods, fibers, or spheres. The size of the metal particles is 5–20 μm . For the ECA to have suitable strength and electrical conduction requires a trade-off in metal filler content. The higher the metal content, the better the electrical conduction, but the poorer the strength of the adhesive. The metal content depends upon whether the adhesive is an isotropic or anisotropic conductor (described below), but does not usually exceed 40% by volume.

The metals most often used in ECAs are silver, gold, nickel, copper or variations of these (such as gold on nickel, silver on glass, or nickel on polymers). Silver-filled ECAs are the most common, because the cost of the metal is moderate and it has good electrical conductivity

and low reactivity with oxygen. Gold has better physical properties than silver but the cost is prohibitive for most applications. Nickel is less expensive, but also has lower conductivity than either Au or Ag and has been found to corrode when aged in a humid environment, resulting in poor adhesion between the nickel and the epoxy matrix. Copper fillers oxidize rapidly and also delaminate from the polymer matrix.

55.8.3 Conduction Mechanisms

The mechanism of conduction in ECAs is hypothesized to occur via percolation, where current travels through a three-dimensional matrix of contacting particles. There must be a sufficient quantity of particles present in the adhesive to provide a suitable conduction path. The bulk resistivity of 60Sn–40Pb solder is $15 \times 10^{-6} \Omega \text{ cm}$, while that of ECAs is 7×10^{-5} to $5 \times 10^{-4} \Omega \text{ cm}$ [55.22]. Therefore, the conduction of solder is 5–33 times better than ECAs. This difference in conductivity is due to the fact that only a portion of the joint cross section is available to provide the percolation path in ECAs whereas the entire cross section of solder joints conducts electricity. The loss of electrical conductivity does not severely affect second-level interconnects but could be an issue for first-level interconnects where good conductivity and switching speed may be required. For the current to pass from one metal particle to another, it must pass through, at a minimum, the oxide that forms on the metals or, at worst, some distance through the polymer matrix. It has been proposed that contact resistance is overcome by tunneling or bulk conduction through the semiconducting metal-oxide layer. However, measured electrical conduction has been determined to be better than any of the mechanisms described above [55.23]. It is possible that, in silver-loaded ECAs, silver diffuses out of the particles into microcracks in the polymer matrix, thereby creating additional conduction paths. To date, the details of the conduction mechanisms remain unresolved.

55.8.4 Isotropic Versus Anisotropic Conduction

ECAs are available in two types of conductors, isotropic and anisotropic. In isotropic adhesives, the conduction path is uniform in all directions with a filler-metal content sufficiently high to create a percolation path for the conductor. Anisotropic ECAs (or AECA, also called z-axis conductors) only have one direction of conduction, useful for fine-pitched applications. In general,

Fig. 55.11 Schematic illustration of an anisotropic electrically conductive adhesive. The adhesive is compressed, causing the conductive particles to contact one another in the z -axis and form an electrical path between the terminal pads. Outside the pad region, the metal particles are separated by the polymer and the AECA acts as a dielectric

anisotropic ECAs are prepared by dispensing metal particles into the polymer matrix at a level far below the percolation threshold. Pressure is imposed on the contact so that the particles come into contact with one another in one direction (parallel to the direction of imposed pressure). In the areas where no pressure is imposed, there is no conduction path and the adhesive is electrically insulated. This is illustrated in Fig. 55.11. In area-array applications anisotropic ECAs can be applied to the board but conduction will only take place between package and mating board pads due to the compression resulting from the cured adhesive, causing particle-to-particle contact between mating pads. No metal particle contact is made beyond the terminal pads, thus the adhesive is an insulator in those areas.

The terminal pad surface to which ECA or AECAs are to be joined must be oxide-free for the adhesive to form a cohesive joint. Bare copper typically provides very poor adhesion [55.24] because adhesives do not wet or react well with metal oxides, and in this

way adhesives are similar to solder alloys. To overcome this problem, copper can be plated with nickel ($\approx 0.5\ \mu\text{m}$) and a thin layer of gold ($\approx 500\ \text{\AA}$). Gold is an excellent bonding surface because it is virtually free of surface oxide and provides a diffusion barrier for nickel. Unlike solders, ECAs do not allow the luxury of using flux to remove oxides during processing so oxide-removal surface treatments must precede dispensing the adhesive. The stability of ECA joints is directly related to the quality of the bond interface with terminal-pad metallizations. In general, the less surface oxide present, the better the electrical stability. If surface oxide is present, there can be de-adhesion at the interface, which results in a reduced ability to carry electrical signals. The bonding of ECAs to other polymers, such as printed wiring board surfaces (FR-4 or polyimide) is excellent. Area-array component requirements are more stringent in the case of ECA joints compared to solder bumps. Solders only wet metal surfaces, so special processing steps are not needed to define solder-joint locations. For ECAs, the method of depositing the ECA must be precise (or an anisotropic ECA used) so that electrical shorts do not occur and this is exacerbated in area-array fine-pitch applications. Also the interconnects cannot easily be inspected because they are hidden beneath the joined component.

55.8.5 Rework

The ability to perform rework on conductive adhesive interconnects may limit the use of these materials for many applications. Thermoplastic adhesives can be reworked by heating and melting the joint, allowing components to be separated from the assembly. Thermosetting bonds are not reversible but can be softened by heating well above T_g and then removed. Some acrylic adhesives can be cleaved at room temperature and physically removed, although the brittle nature of the acrylics that allows for removal may also represent too great a joint reliability risk.

55.9 Thermal Issues

55.9.1 Thermal Issues in Digital Packaging

Increasing circuit and component density creates thermal complications that must be resolved by the packaging solution. Excessive temperatures in the de-

vices result in degraded circuit performance or reliability issues. The thermal performance can be improved by using packaging materials with high thermal conductivity.

The operating temperature of Si directly impacts on switching speed and timing. In the operating temperature

range of 50–100 °C, a 5 °C drop in operating temperature results in a 1% increase in CMOS switching speed. From a reliability perspective, each 10 °C increase in operating temperature results in a twofold increase in the die failure rate. Therefore, packaging materials and processes that improve thermal performance are very important.

New materials is the area where the most significant improvements in thermal performance is possible. Improved thermal interface materials (greases, adhesives, tapes, phase-change materials) will improve heat flow out of the package. Improved adhesives and compliant sheets inside the package will improve heat dissipation from the die and can better accommodate CTE mismatch strains within the package.

Composite materials for package lids, heat spreaders and heat sinks are needed. Currently, these components face a dilemma of conflicting materials properties as good materials with good thermal conduction (e.g., Al) have very high CTE (e.g., $\text{Al} = 25 \times 10^{-6} / ^\circ\text{C}$), which can result in poor reliability. Furthermore, most low-cost thermal conductors are also electrical conductors, which makes their use in dielectric packages problematic. The development of composite materials with anisotropic conductivities can provide excellent thermal conduction with matched CTE and the potential for good electrical isolation. At the die level, the use of low-cost thin-film diamond must increase. Diamond has excellent thermal conductivity and isolation but is currently too expensive for extensive use in microelectronic packaging.

55.10 Summary

Materials are one of the most important aspects of microelectronic packaging. There is a need for new materials to be developed to meet the ever-changing requirements of high-speed digital and RF applications. Considerable resources are required to develop and characterize these materials. These materials must also be tested to determine their compatibility with assembly processes and

55.9.2 Thermal Issues in RF Packaging

RF die can generate a great deal of heat when operating at high frequencies. This is particularly an issue with GaAs die because it has poor thermal conductivity (30 W/mK). The generated heat must be dissipated through the package. The preferred method to remove heat from wirebonded GaAs die is to thin the GaAs wafer by back-grinding to 100–125 μm . The thinner the die, the easier it is to transmit heat through the GaAs. Through-die vias are also used to help dissipate heat. The vias are formed by laser-drilling holes through the GaAs then plating the side walls with Au then thinning the wafer. Thinning the wafer not only benefits heat dissipation but also reduces the distance from the conducting layer on the surface of the die to the ground plane on the die backside, which improves impedance match in microstrip designs.

The problems with through-die vias and wafer thinning are cost and die breakage. Laser-drilling and thinning process increase the cost of the die. Furthermore, GaAs is a very brittle material and the presence of vias and thinning exacerbates the potential for cracking.

One method to reduce the thermal and mechanical problems associated with thermal issues on GaAs is to use flip-chip interconnects. For flip chip, the bumps act as electrical, mechanical and thermal interconnects. The bumps are on the front side of the die so full-thickness die can be used. The challenge with flip chip as a thermal conductor is to put sufficient numbers of bumps on the die to dissipate the heat.

device performance and to meet industry standards. The fundamental materials characteristics that must be understood, depending upon the material, include: the dielectric constant, dielectric loss, conductivity, resistivity, moisture absorption, glass-transition temperature, strength, time-dependent deformation (creep), and fracture toughness.

Acknowledgements

1 Perspectives on Electronic and Optoelectronic Materials by Tim Smeeton, Colin Humphreys

Many thanks to Dr Ron Broom for his helpful comments on this manuscript.

A.5 Defects in Monocrystalline Silicon by Wilfried von Ammon

The author is greatly indebted to W. Haeckl, E. Dornberger, D. Gräf and R. Schmolke for many helpful discussions and for providing some of the figures.

A.7 Photoconductivity in Materials Research by Monica Brinza, Jan Willekens, Mohammed L. Benkheldir, Guy J. Adriaenssens

The authors are grateful to the *Fonds voor Wetenschappelijk Onderzoek – Vlaanderen* for its financial support of their research.

A.9 Charge Transport in Disordered Materials by S. D. Baranovskii, O. Rubel

The authors are indebted to numerous colleagues for stimulating and enlightening discussions. Among those are Boris Shklovski (University of Minnesota), Alexei Efros and Michael Raikh (Utah University), Hellmut Fritzsche (Chicago University), Peter Thomas, Walther Fuhs and Heinz Bässler (Philipps-University Marburg), Igor Zvyagin (Moscow State University) and many other colleagues. Financial support of the Deutsche Forschungsgemeinschaft is gratefully acknowledged.

A.11 Ionic Conduction and Applications by Harry L. Tuller

Support from the National Science Foundation (Grant Nos. DMR-0243993 and ECS-0428696) and ARO-MURI under grant DAAD-0101-0566 for topics related to this work are highly appreciated. In assembling this work, I drew on earlier journal and proceedings articles published by myself or in conjunction with colleagues. In particular, I wish to acknowledge my collaborator in Ref. 2, Prof. P. Knauth of the Université de Provence, Marseille, France.

B.17 Structural Characterization by Paul D. Brown

As ever, there are many people one wishes to acknowledge for their involvement in the growth, processing

and underpinning characterisation research programmes drawn from to illustrate this chapter. University of Nottingham: with thanks to Tom Foxon, T.S. Cheng, Sergei Novikov and Chris Statton for the provision of MBE GaN samples and supporting XRD analysis; and to Mike Fay for GaAs CBED patterns. University of Cambridge: with thanks to Colin Humphreys for provision of instrumentation; Chris Boothroyd for EDX and HAADF data on the SiGe samples; Michael Natusch for GaN EELS data; Robin Taylor for RHEED stage development; David Tricker for the Si-doped GaN micrograph; and Yan Xin for the GaN images used for dislocation analysis. University of Warwick: with thanks to Richard Kubiak and E.H.C. Parker for supplying SiGe/Si samples. Polish academy of Sciences, Warsaw: with thanks to Jan Weyher for homoepitaxial GaN samples. With thanks also to the EPSRC for funding support.

B.19 Thermal Properties and Thermal Analysis: Fundamentals, Experimental Techniques and Applications by S.O. Kasap

The authors thank NSERC for financial support.

B.20 Electrical Characterization of Semiconductor Materials and Devices by M. Jamal Deen, Fabien Pascal

The authors are very grateful to Drs. O. Marinov and D. Landheer for their careful review of the manuscript and their assistance. They are also grateful to several previous students and researchers whose collaborative research is discussed here. Finally, they are grateful to NSREC of Canada, the Canada Research Chair program and the CNRS of France for supporting this research.

C.23 Gallium Arsenide by Mike Brozel

The author is delighted to acknowledge the help given to him over many years by his colleagues and friends both at UMIST and in industry. Specifically, he wishes to thank R. Blunt, I.R. Grant, and R. H. Wallis for their careful and critical reading of this manuscript.

C.24 High-Temperature Electronic Materials: Silicon Carbide and Diamond*by Magnus Willander, Milan Friesel, Qamar-ul Wahab, Boris Straumal*

Magnus Willander and Milan Friesel would like to thank Dr. V. Narayan for checking the text, and Dr. A. Baranzahi for letting us use Figs. 24.2–24.3. Qamar-ul Wahab thanks Mr. Amir Karim for all his support.

C.25 Amorphous Semiconductors: Structure, Optical, and Electrical Properties*by Kazuo Morigaki, Chisato Ogiwara*

We wish to thank M. Ichihara, K. Suzuki and M. Yamaguchi, Institute for Solid State Physics, University of Tokyo, for providing us with their unpublished materials (Fig. 25.7a,b). Stimulating and helpful discussions were held with Prof. S. Kugler during the stay of one of us (K.M.) at the Budapest University of Technology and Economics, for which K.M. is grateful.

C.28 Dielectric Materials for Microelectronics*by Robert M. Wallace*

RMW gratefully acknowledges the many discussions and hard work of his colleagues and students engaged in gate-stack research. This work is supported in part by the Texas Advanced Technology Program and the Semiconductor Research Corporation.

C.29 Thin Films*by Robert D. Gould[†]*

The author wishes to acknowledge the general support and encouragement of Prof. C. A. Hogarth, Department of Physics, Brunel University, and of Prof. W. Fuller, Department of Physics, Keele University. Particular thanks are also due to Prof. E. W. Williams, Electronic Engineering Group, Keele University for collaborative work and permission to reproduce Figs. 29.6 and 29.7.

D.33 Electron Transport Within the III–V Nitride Semiconductors, GaN, AlN, and InN: A Monte Carlo Analysis*by Brian E. Foutz, Stephen K. O'Leary, Michael Shur, Lester F. Eastman*

Financial support from the Office of Naval Research and the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged. The use of equipment granted from the Canada Foundation for Innovation, and equipment loaned from the Canadian Microelectronics Corporation, is also acknowledged.

D.36 II–VI Narrow-Bandgap Semiconductors for Optoelectronics*by Ian M. Baker*

The author wishes to express his gratitude to Mike Kinch of DRS Technologies, Kadri Vural and Jose Arias of Rockwell/Boeing and Marion Reine and coworkers at BAE SYSTEMS, Lexington for supplying material for this chapter and valuable advice. Also the advice and support from my technical colleagues, particularly: Peter Capper, Chris Maxey, Chris Jones and Les Hipwood, and my management here at SELEX Infrared, particularly Graham Hall. Thanks also to my wife, Lesley, for help with the English.

D.37 Optoelectronic Devices and Materials*by Stephen Sweeney, Alfred Adams*

It is a pleasure to acknowledge the many people with whom the authors have worked with over the years. In particular, we would like to thank the staff and students, past and present, at the University of Surrey for their wide-ranging contributions to this work. We would also like to thank the editor, Safa Kasap, for his support and encouragement in preparing this chapter. On a personal note, SJS would like to thank his wife for her support whilst writing this chapter.

D.44 Optical Nonlinearity in Photonic Glasses*by Keiji Tanaka*

The author would like to thank his students, K. Sugawara and N. Minamikawa, for preparing illustrations and giving comments.

E.48 Photoconductors for X-Ray Image Detectors*by M. Zahangir Kabir, Safa Kasap, John Rowlands*

We would like to thank Dr. Randy Luhta for useful discussions. We acknowledge financial support from NSERC.

E.52 High-Temperature Superconductors*by Rainer Wesche*

I wish to thank P. Bruzzone for his support and encouragement. The careful reviewing and many constructive suggestions on the manuscript by J.F. Crawford are especially appreciated.

E.53 Molecular Electronics*by Michael Petty*

The author would like to thank the staff and students of, and visitors to, the Durham Centre for Molecular and Nanoscale Electronics, who have contributed to some of work described in this chapter. Particular thanks are due

to Fraser Stoddart for useful discussions on the rotaxane switching devices and for providing Fig. 53.17a. Thanks are also due to Karl Coleman for providing the drawings of carbon nanotubes, Fig. 53.7.

E.54 Organic Materials for Chemical Sensing

by Asim Kumar Ray

The authors are grateful to the Engineering & Physical Research Council (UK) and the European Union for financial support of their work over the last 20 years.

Gratitude is also due to Dr. S. C. Thrope of the Health Safety Executive (UK), Dr. M. Hofton of TQ Environmental Plc., Prof. K. C. Thompson of ALControl and Dr. F. A. Grunfeld of NIMA Technology for their collaboration and support. Prof. M. J. Cook of the University of East Anglia remains a generous provider of novel phthalocyanine compounds for sensing experiments over the years. Above all, the contributions from Drs. R. Capan, O. Omar and A. V. Nabok are acknowledged with gratitude.

About the Authors

Martin Abkowitz

Webster, NY, USA
mabkowitz@mailaps.org,
abkowitz@chem.chem.rochester.edu

Chapter D.39

Martin A. Abkowitz received his Ph.D. in Physics from Syracuse University in 1964. During the period 1964–65, Abkowitz was Andrew Mellon Postdoctoral Fellow in Physics at the University of Pittsburgh. In 1965, Abkowitz joined the Webster Research Center (now the Wilson Center for Research and Technology) of Xerox Corporation where he was a Principal Scientist until retirement in 1999. Abkowitz is currently a Visiting Scientist at the University of Rochester. He is a fellow of the American Physical Society. He has 174 publications including 35 US patents. Abkowitz has made over 250 contributed and invited presentations at international conferences.

Sadao Adachi

Gunma University
 Department of Electronic Engineering,
 Faculty of Engineering
 Gunma, Japan
adachi@el.gunma-u.ac.jp

Chapter D.31

Sadao Adachi received his Ph.D. from Osaka University and is Professor of Electrical Engineering at Gunma University. From 1980 to 1988 he was with NTT Electrical Communication Laboratories, Japan. He has published and presented over 200 technical papers and 20 textbooks on semiconductor physics and technology. His current research interests include physical properties of semiconductors and new functional materials.

Alfred Adams

University of Surrey
 Advanced Technology Institute
 Surrey, UK
alf.adams@surrey.ac.uk

Chapter D.37

Alfred Adams studied at Leicester University, UK, and in 1964 embarked on postdoctoral research at the University of Karlsruhe, Germany. His work on III–V semiconductors started in 1967 at the University of Surrey where he is now a Distinguished Professor. He received the Duddell medal from the Institute of Physics in 1995 for proposing the use of strained quantum wells in III–V lasers and was elected Fellow of the Royal Society in 1996.

Guy J. Adriaenssens

University of Leuven
 Laboratorium voor Halfgeleiderfysica
 Leuven, Belgium
guy.adri@fys.kuleuven.ac.be

Chapter A.7

Guy Adriaenssens received his Ph.D. from the University of Washington, Seattle, in 1971. After a postdoctoral stay at the University of the Saarland, Germany, he joined the University of Leuven, Belgium, in 1973. His current research interests center on transport properties and the electronic density of states of amorphous semiconductors and chalcogenide glasses.

Wilfried von Ammon

Siltronic AG
 Research and Development
 Burghausen, Germany
wilfried.ammon@siltronic.com

Chapter A.5

Dr. von Ammon studied physics at the Technical University of Munich and the University of Regensburg. In 1981, he received his Ph.D. in physics from the University of Regensburg. In 1982, he joined Wacker Siltronic and has been working in research and development since then. His main focus was on silicon crystal growth (floating zone and Czochralski method), silicon-layer growth by chemical vapor deposition, neutron transmutation doping, thermal treatment of silicon and behavior of defects in silicon. In 1994, he managed a research project in collaboration with Sematech, USA, to assess 400 mm technology for the decision on the next-generation wafer. During recent years he has primarily been working on the development and improvement of 300 mm crystal-growth processes and on defect engineering of the silicon bulk.

Peter Ashburn

University of Southampton
School of Electronics
and Computer Science
Southampton, UK
pa@ecs.soton.ac.uk

Chapter C.22

Peter Ashburn received a Ph.D. degree in electrical and electronic engineering in 1974 from the University of Leeds and then joined the Philips Research Laboratories. In 1978 he joined the University of Southampton and is currently a Professor of Microelectronics. His research interests include SiGe heterojunction bipolar transistors (HBTs), ultimate CMOS and carbon nanotubes. He has published over 200 papers in the scientific literature and has authored two books on bipolar transistors.

Mark Auslender

Ben-Gurion University
of the Negev Beer Sheva
Department of Electrical
and Computer Engineering
Beer Sheva, Israel
marka@ee.bgu.ac.il

Chapter C.21

Mark Auslender received a Ph.D in solid-state theory in 1977. He was a senior researcher at Institute of Metal Physics, Ural Branch of the Academy of Sciences of the USSR. In 1991 he joined the Microelectronics Laboratory at the Department of Electrical and Computer Engineering, Ben-Gurion University of the Negev, Israel as a grade A researcher. His present interests focus on micro- and nanometer-scale diffraction gratings, optical coherence in regular and disordered media.

Darren M. Bagnall

University of Southampton
School of Electronics
and Computer Science
Southampton, UK
dmb@ecs.soton.ac.uk

Chapter C.22

Dr. Darren Bagnall is a senior lecturer in the School of Electronics and Computer Science at Southampton University. His research has included pioneering work on molecular-beam epitaxy (MBE) and chemical vapor deposition (CVD) for the development of new nano and quantum devices based on ZnO, silicon and silicon germanium. He has published over 50 refereed papers.

Ian M. Baker

SELEX Sensors
and Airborne Systems Infrared Ltd.
Southampton, Hampshire, UK
ian.m.baker@selex-sas.com

Chapter D.36

Ian Baker received a Ph.D. in solid-state imaging devices at Southampton University in 1973. His career in solid-state imaging has spanned the development of visible imaging charge-coupled devices (CCDs) within Philips and second- and third-generation infrared detectors at various companies. He has published over 75 papers and has over 30 patents in the field of electro-optics. His current interest is the development of advanced third-generation infrared detectors, including 3D imaging.

Sergei Baranovskii

Philipps University Marburg
Department of Physics
Marburg, Germany
baranovs@staff.uni-marburg.de

Chapter A.9

Professor Sergei Baranovskii received his Ph.D. (1981) in theoretical physics from the Ioffe Physical-Technical Institute of the Russian Academy of Sciences in St. Petersburg, where he worked as a senior researcher until 1990. Since 1990 he has been working at the Philipps University Marburg, Germany, where he got a Habilitation in Theoretical Physics in 1995. His research interests are devoted to charge transport and optical properties of organic and inorganic disordered solids.

Mark Baxendale

Queen Mary, University of London
Department of Physics
London, UK
m.baxendale@qmul.ac.uk

Chapter E.50

Mark Baxendale is a Reader in Nanotechnology at Queen Mary, University of London since 2002. The focus of his research is the physics and applications of carbon nanotubes. These applications include molecular quantum electronic devices, probes for scanning probe microscopy and single-molecule detection.

**Mohammed L. Benkhedir**

Chapter A.7

University of Leuven
Laboratorium voor Halfgeleiderfysica
Leuven, Belgium
MohammedLoufti.Benkhedir
@fys.kuleuven.ac.be

Mohammed Benkhedir received an M.S. in Physics from the University of Annaba, Algeria, and holds a Lectureship at the Centre Universitaire de Tebessa, Algeria. He is currently studying the electronic properties and density of states in amorphous selenium by means of photoconductivity techniques at the University of Leuven, Belgium.

**Monica Brinza**

Chapter A.7

University of Leuven
Laboratorium voor Halfgeleiderfysica
Leuven, Belgium
monica.brinza@fys.kuleuven.ac.be

Monica Brinza received an M.S. in Physics from the University of Bucharest, Romania and a Ph.D. from the University of Leuven, Belgium. Her current research interests focus on the transport properties of materials for photovoltaic applications and the electronic density of states of amorphous semiconductors and chalcogenide glasses.

Paul D. Brown

Chapter B.17

University of Nottingham
School of Mechanical, Materials
and Manufacturing Engineering
Nottingham, UK
paul.brown@nottingham.ac.uk

Paul D. Brown received a Ph.D. in Applied Physics from the University of Durham in 1989. He is presently Reader in Materials Characterisation at the University of Nottingham. His present research interests are concerned with the interrelationship between the structure, property and processing of structural, functional and biomedical materials, assessed using a broad range of characterisation techniques, with emphasis on novel variants of electron microscopy.

Mike Brozel

Chapter C.23

University of Glasgow
Department of Physics and Astronomy
Glasgow, UK
mikebrozel@beeb.net

For most of his career, Mike Brozel has worked on the growth and assessment of semiconductors. Present investigations include instrumentation for the mapping of bulk GaAs and novel structures for silicon nuclear particle detectors. An author of over 100 papers, he was the co-author with G. E. Stillman of *Properties of Gallium Arsenide*, 3rd ed. and recently co-authored a chapter on GaAs in *Bulk Crystal Growth*.

**Lukasz Brzozowski**

Chapter D.45

University of Toronto
Sunnybrook and Women's Research
Institute, Imaging Research/ Department
of Medical Biophysics
Toronto, ON, Canada
lukbroz@sten.sunnybrook.utoronto.ca

Lukasz Brzozowski has extensive experience in optics, medical imaging, nanotechnology and product development. He is currently leading research on the development of a combined X-ray/magnetic resonance imaging (MRI) system, and on the application of photo-excitable quantum dots for the treatment of cardiovascular disease. Dr. Brzozowski was awarded the Governor General's Gold Medal for the best applied Ph.D. from the University of Toronto in the year 2003.

**Peter Capper**

Chapters B.12, B.14, B.15

SELEX Sensors
and Airborne Systems Infrared Ltd.
Materials Team Leader
Southampton, Hampshire, UK
pete.capper@selex-sas.com

Peter Capper has spent some 30 years in the infrared industry growing and characterising cadmium mercury telluride (CMT) and other tellurium-based materials. He holds a patent in the bulk growth of CMT, has authored/co-authored over 100 papers and given several invited talks at international crystal growth/infrared (IR) conferences. He has edited/co-edited five books in IR materials and devices and crystal growth.

Larry Comstock

San Jose State University
San Jose, CA, USA
Comstock@email.sjsu.edu

Chapter E.51

R. Lawrence Comstock, Ph.D, has over 28 years of experience in computer storage system development. He was an IBM engineering manager for 25 years and was Vice President, Advanced Recording Technology at Maxtor Corporation. He received his Ph.D. in electrical engineering from Stanford University, and is the author of several books and publications. Larry has been teaching courses to graduate students at institutions such as Stanford University since 1993. He received the IEEE Fellow Award for Developments in Magnetic Storage and Magnetic Microwave Devices.

Ray DeCorby

University of Alberta
Department of Electrical
and Computer Engineering
Edmonton, Alberta, Canada
rdecorby@trlabs.ca

Chapter D.43

Ray DeCorby received his M.Sc. degree in Electrical Engineering from the University of Saskatchewan in 1995, and his Ph.D. degree in Electrical and Computer Engineering from the University of Alberta in 1998. Currently, he is an Associate Professor of Electrical and Computer Engineering at the University of Alberta. His research interests include integrated optics on silicon platforms, photonic glasses and polymers, and integrated nonlinear optics.

M. Jamal Deen

McMaster University
Department of Electrical and Computer
Engineering (CRL 226)
Hamilton, Canada
jamal@mcmaster.ca

Chapter B.20

M. Jamal Deen is Professor and Senior Canada Research Chair in Information Technology at McMaster University, Canada. His research work is documented in 14 invited book chapters, six awarded patents, and more than 300 peer-reviewed articles. His current research interests are in microelectronics and optoelectronics. Dr. Deen was a Fulbright–Laspau Scholar, an American Vacuum Scholar, won the Electrochemical Society (ECS) Callinan Award and the Distinguished Researcher Award from the Province of Ontario. He is a fellow of the IEEE, fellow of the EIC (Engineering Institute of Canada) and a fellow of the ECS.

Leonard Dissado

The University of Leicester
Department of Engineering
Leicester, UK
lad4@le.ac.uk

Chapter A.10

Professor Dissado was awarded a D.Sc. in 1990 by The University of London for his work on the theory of dielectric response and electrical breakdown phenomena. His research interests in dielectric response covers a wide range of materials from glasses and high voltage insulators, to bio-tissues. He is also co-author of the book *Electrical Degradation and Breakdown in Polymers*.

David Dunmur

University of Southampton
School of Chemistry
Southampton, UK
d.a.dunmur@soton.ac.uk

Chapter D.38

David Dunmur received his D.Phil. degree from the University of Oxford in 1965. His research over more than 30 years has been concerned with the physical properties of liquid crystals, specifically their dielectric, optical, electro-optical and elastic properties. He was founding editor of *Liquid Crystals Today*, and the 1999 recipient of the G. W. Gray Medal of the British Liquid Crystal Society. Professor Dunmur is an Emeritus Professor of Chemistry at the University of Sheffield, and currently a Visiting Professor at the University of Southampton.

Lester F. Eastman

Cornell University
Department of Electrical
and Computer Engineering
Ithaca, NY, USA
lfe2@cornell.edu

Chapter D.33

Lester F. Eastman is presently the John L. Given Foundation Chair Professor of Engineering at Cornell University. He joined the faculty of Electrical Engineering at Cornell in 1957, and also serves as a member of the graduate fields of Applied Physics and Materials Science. Since 1965 he has been doing research on compound semiconductor materials, high-speed devices and circuits, and has been active in organizing workshops and conferences on these subjects elsewhere since 1965 and at Cornell from 1967. He has supervised over 100 Ph.D. theses, over 50 M.S. theses, and over 50 postdoctoral studies. In his research group effort is underway on molecular-beam epitaxy, microwave transistors, high-speed semiconductor lasers, and fundamental phenomena in compound semiconductor quantum electron and optical devices. In 1991 he was awarded the GaAs Symposium Award and the Heinrich Welker medal. He was awarded the Alexander von Humboldt Senior Fellowship in 1994, and the Aldert van der Ziel Award in 1995. The IEEE honored him with their 1999 Graduate Teaching Award and Third Millennium Medal 2000. He was recently elected Fellow of the American Physical Society, 2001 and received the University of Michigan's William Gould Dow Lectureship award the same year. The biennial IEEE Cornell Conference on High-Performance Devices was renamed the IEEE Lester Eastman Conference in 2002. The Electron Devices Society has selected him for the 2002 recipient of the IEEE Electron Devices Society J. J. Ebers. Award. Distinguished Educator Award, 2003, for IEEE Microwave Theory and Technique Society.

Andy Edgar

Victoria University
School of Chemical
and Physical Sciences SCPS
Wellington, New Zealand
Andy.Edgar@vuw.ac.nz

Chapter D.40

Dr. Edgar is an Associate Professor in the School of Chemical and Physical Sciences at Victoria University, Wellington, New Zealand, and a Principal Investigator of the MacDiarmid Institute. His current research interests are storage phosphors for radiation imaging, and glass ceramics for optoelectronic applications.

Brian E. Foutz

Cadence Design Systems
Endicott, NY, USA
foutz@cadence.com

Chapter D.33

Brian E. Foutz is currently a Senior Member of Consulting Staff with Cadence Design Systems. Dr. Foutz's current research focuses on ASIC design-for-test strategies. Dr. Foutz is currently a member of the Institute of Electrical and Electronics Engineers.

Mark Fox

University of Sheffield
Department of Physics and Astronomy
Sheffield, UK
mark.fox@shef.ac.uk

Chapter D.42

Dr. Fox obtained his D.Phil. degree in physics from Oxford University in 1987. After post-doctoral work at AT&T Bell Laboratories, he was a Royal Society University Research Fellow at Oxford until 1998, when he took up his present post as a Reader in Physics at Sheffield University. His research interests include low-dimensional semiconductor structures, quantum optics and ultrafast laser spectroscopy.

Darrel Frear

RF and Power Packaging Technology
Development, Freescale Semiconductor
Tempe, AZ, USA
darrel.frear@freescale.com

Chapter E.55

Darrel Frear has an A.B. in Engineering Science from Dartmouth College and M.S. and Ph.D. degrees in Materials Science from the University of California, Berkeley. He is manager of Radio-frequency (RF) and Power Packaging Technology Development at Freescale Semiconductor. Previously, Darrel was at Sandia National Labs. Darrel's background includes materials research and development to enhance processing and reliability of electronic components.

Milan Friesel

Chapter C.24

Chalmers University of Technology
Department of Physics
Göteborg, Sweden
friesel@chalmers.se

Milan Friesel obtained his Ph.D. in Experimental High-Pressure Physics from Chalmers University of Technology in Göteborg in 1987. From 1988 to 1991 he was guest researcher at the Max Planck Institute for Metal Research in Stuttgart. Since 1994 he is Associate Professor in physics at the SIMS laboratory, Chalmers University of Technology. His research interests are superionic conductors, metals and alloys, semiconductors and characterization by the SIMS technique.

Jacek Gieraltowski

Chapter A.4

Université de Bretagne Occidentale
29285 Brest Cedex, France
Jacek.Gieraltowski@univ-brest.fr

Professor Gieraltowski holds a DSc. from Warsaw University (Poland) on the basis of research done in a French CNRS laboratory in Meudon, Bellevue (Paris, France). He has been involved in research on magnetic materials (ferrites, thin films and nanowires) for more than 30 years with numerous journal papers. After several years as a senior researcher in the Res. Lab. of Polfa in Warsaw associated with the Polish Academy of Science in Warsaw, he joined the department of Physics, in Brest (France) as an assistant professor working on the physics of ferrites and magnetic materials for microwave devices. Presently, he is full professor of Physics in Brest, working on fast switching magnetization problems for high density magnetic recording, giant magnetoimpedance sensors and the application of magnetism to biological and medical applications.

Yinyan Gong

Chapter D.35

Columbia University
Department of Applied Physics
and Applied Mathematics
New York, NY, USA
yg2002@columbia.edu

Yinyan Gong is graduate student of Columbia University. Her Current research interests are optical and electrical properties as well as microstructures of wide-band-gap materials. She received a Guanhua fellowship from Shanghai Jiao Tong University in 1997/1998.

Robert D. Gould[†]

Chapter C.29

Keele University
Thin Films Laboratory, Department of
Physics, School of Chemistry and Physics
Keele, Staffordshire, UK

Dr. Robert Gould has received two doctorates from Brunel University, a Ph.D. degree in 1973, and a D.Sc. degree in 2000 for his contribution to knowledge in the physics and technology of thin films. He spent four years lecturing in Physics at the University of Science, Malaysia, before joining Keele University in 1980, where he is currently a Senior Lecturer in Physics. He has published extensive review articles on electrical conduction in both phthalocyanines and cadmium compounds, and also on high-field conduction in nanostructures. He also has research interests in insulating nitride films prepared by sputtering. Dr. Robert Gould died suddenly on March 16, 2006 and will be greatly missed by the scientific community. *Editors.*

Shlomo Hava

Chapter C.21

Ben-Gurion University
of the Negev Beer Sheva
Department of Electrical
and Computer Engineering
Beer Sheva, Israel
hava@ee.bgu.ac.il

Shlomo Hava received a Ph.D. in Electrical Engineering from the University of Delaware in 1982. Since then he has worked at the Department of Electrical and Computer Engineering at Ben-Gurion University of the Negev, Israel. Currently he is a faculty professor and head of the Microelectronics Laboratory at this department. His present research interests include micro- and nanometer-scaled diffraction gratings in optical elements and light emitters, and the effects of gamma radiation and vacuum on optoelectronic devices.

Colin Humphreys

University of Cambridge
Department of Materials Science
and Metallurgy
Cambridge, UK
colin.Humphreys@msm.cam.ac.uk

Chapter .1

Colin Humphreys is the Goldsmiths' Professor of Materials Science at Cambridge University. He is the Director of the Cambridge Centre for Gallium Nitride and has published over 500 research papers, mainly on electron microscopy and analysis, semiconductors, superconductors and high-temperature alloys. He has received various national and international medals and awards for his research.

Stuart Irvine

University of Wales, Bangor
Department of Chemistry
Gwynedd, UK
sjc.irvine@bangor.ac.uk

Chapters B.14, E.46

Professor Irvine is a Chartered Physicist and received his B.Sc degree in Physics from Loughborough University of Technology, Ph.D. in Physical Metallurgy and Science of Materials, and D.Sc. in Physics, both from the University of Birmingham. His research covers various aspects of metalorganic chemical vapor deposition (MOCVD) of compound semiconductor and oxide materials for applications such as solar cells, detectors and displays. This research has led to the development of new optical in situ monitoring devices that are now manufactured and sold worldwide. Previous appointments include Rockwell Science Centre and the Royal Signals and Radar Establishment, Malvern where he carried out pioneering research in MOCVD of II–VI semiconductors.

Minoru Isshiki

Tohoku University
Institute of Multidisciplinary Research
for Advanced Materials
Sendai, Japan
ishiki@tagen.tohoku.ac.jp

Chapters B.16, D.34

Minoru Isshiki is a Professor at the Tohoku University in the Institute of Multidisciplinary Research for Advanced Materials. He earned his Ph. D. in materials science at Tohoku University in 1976. Dr. Isshiki is working on the purification of metals, single-crystal growth of bulk and thin-film compound semiconductors and impurity effects on their properties.

Robert Johanson

University of Saskatchewan
Department of Electrical Engineering
Saskatoon, SK, Canada
johanson@engr.usask.ca

Chapter A.2

Robert Johanson is currently an Associate Professor in the Department of Electrical Engineering at the University of Saskatchewan, Canada. He obtained his A.B. (honors) (1981), M.Sc. (1983) and Ph.D. (1991) from the University of Chicago, and subsequently worked as a postdoctoral research fellow and a research associate at the University of Saskatchewan. His research interests include electrical and optical properties of amorphous semiconductors, and glasses. Dr. Johanson has published numerous journal and conference papers in this field, and is a member of the American Physical Society and the IEEE.

Tim Joyce

University of Liverpool
Functional Materials Research Centre,
Department of Engineering
Liverpool, UK
t.joyce@liv.ac.uk

Chapter B.14

Tim Joyce has worked on semiconductor epitaxy since obtaining his B.Sc. in 1981 and was awarded a Ph.D. in Materials Science in 1991 at the University of Liverpool for research in metalorganic molecular-beam epitaxy (MOMBE). Current research interests include MBE of group III–N and group III–V–N semiconductors. He is currently chairman of the British Association of Crystal Growth.

M. Zahangir Kabir

Concordia University
Department of Electrical
and Computer Engineering
Montreal, Quebec, Canada
kabir@encs.concordia.ca

Chapter E.48

Zahangir Kabir received the B.Sc. and M.Sc. degrees in Electrical and Electronic Engineering from Bangladesh University of Engineering and Technology (BUET), Bangladesh, in 1994 and 1996, respectively. From 1996 to 2000 he was an Assistant Professor with the Electrical and Electronic Engineering department at BUET. He received his PhD from the University of Saskatchewan in 2005, and is currently Assistant Professor at Concordia University in Montreal. His research interests are in the areas of imaging sensors, disordered semiconductors, and electronic materials and devices.

Safa Kasap

University of Saskatchewan
Department of Electrical Engineering
Saskatoon, SK, Canada
safa.kasap@usask.ca

Chapters [A.2](#), [A.3](#), [B.19](#), [E.48](#)

Safa Kasap is currently a Professor and Canada Research Chair in Electronic Materials and Devices in the Electrical Engineering Department at the University of Saskatchewan, Canada. He obtained his B.Sc. (1976), M.Sc. (1978) and Ph.D. (1983) degrees from the Imperial College of Science, Technology and Medicine, University of London, specializing in amorphous semiconductors and chalcogenide glasses. In 1996 he was awarded the D.Sc. (Engineering) from London University for his research contributions to materials science in electrical engineering. He is a fellow of the Institution of Electrical Engineers, the Institute of Physics and the Institute of Materials. His research interests are in amorphous semiconductors, glasses for photonics, photoconductors, electrical, optical and thermal properties of materials, and related topics, with more than one hundred refereed journal papers in these areas. He is the author of *Optoelectronics and Photonics: Principles and Practices* and *Principles of Electronic Materials and Devices*, both textbooks are widely used by many major universities and professionals.

Alexander Kolobov

National Institute of Advanced Industrial
Science and Technology
Center for Applied
Near-Field Optics Research
Ibaraki, Japan
a.kolobov@aist.go.jp

Chapter [E.49](#)

Dr. A. V. Kolobov obtained his Ph.D. from the A. F. Ioffe Physico-Technical Institute at St. Petersburg, Russia. Since 1994 he has been a senior researcher at the National Institute of Advanced Industrial Science and Technology (AIST) in Japan. His current interests include, but are not limited to, amorphous semiconductors, photoinduced phenomena in solids, optical data storage and use of synchrotron radiation in materials science.

Cyril Koughia

University of Saskatchewan
Department of Electrical Engineering
Saskatoon, SK, Canada
kik486@mail.usask.ca

Chapters [A.2](#), [A.3](#)

Cyril Koughia received his Ph.D. from the A. F. Ioffe Physico-Technical Institute, St. Petersburg, Russia and is a Research Associate at the University of Saskatchewan, Canada. His current research interests include the physical properties of amorphous semiconductors and glasses used in photonics and electronics.

Igor L. Kuskovsky

Queens College,
City University of New York (CUNY)
Department of Physics
Flushing, NY, USA
igor_kuskovsky@qc.edu

Chapter [D.35](#)

Igor L. Kuskovsky is an Assistant Professor of Physics at Queens College, CUNY. Research interests include optical and magneto-optical properties of quantum dots and nanowires, applications of low dimensional systems for bio-imaging, and microstructural, electrical and electro-optical properties of wide-band-gap semiconductors. Previously, he has done extensive work on optical properties of II–VI wide-band-gap semiconductors.

Geoffrey Luckhurst

University of Southampton
School of Chemistry
Southampton, UK
g.r.luckhurst@soton.ac.uk

Chapter [D.38](#)

Geoffrey Luckhurst was awarded his Ph.D. degree in 1965 from the University of Cambridge having studied for his B.Sc. at the University of Hull. His research into liquid crystals started in Cambridge and continues at Southampton where he is the Emeritus Professor of Chemical Physics. His work is concerned with many aspects of this interdisciplinary field including the design of novel materials, their molecular orientational order, the molecular dynamics, their macroscopic order and dynamics using both experimental and theoretical techniques. He is co-founder of the international journal, *Liquid Crystals*, was the recipient of the G. W. Gray Medal of the British Liquid Crystal Society in 2002 and was elected President of the International Liquid Crystal Society of which he is an Honoured Member.

**Akihisa Matsuda**

Chapter C.26

Tokyo University of Science
Research Institute for Science
and Technology
Chiba, Japan
amatsuda@rs.noda.tus.ac.jp, matsuda@aist.go.jp

Dr. Akihisa. Matsuda has an M.S. degree from Waseda University, a Ph.D. from the Tokyo Institute of Technology, and is Chief Senior Researcher at ETL MITI Japan. He is also the Director of the Research Initiative for Thin-Film Silicon Solar-Cells AIST Japan.

**Naomi Matsuura**

Chapter D.41

Sunnybrook Health Sciences Centre
Department of Medical Biophysics,
Imaging Research
Toronto, ON, Canada
matsuura@sri.utoronto.ca

Naomi Matsuura received her Ph.D. from the University of Toronto in 2003 for the development of 2D and 3D periodic, three-dimensional nanoscale architectures using non-lithographic parallel patterning technologies. Dr. Matsuura is currently a Canadian Institutes of Health Research (CIHR) Strategic Training Fellow in the EIRR21st Program at Toronto's Sunnybrook Health Sciences Centre, and is investigating the development of novel nanostructures for cancer imaging and therapy.

Kazuo Morigaki

Chapter C.25

University of Tokyo
Tokyo, Japan
k.morigaki@yacht.ocn.ne.jp

Kazuo Morigaki received his Ph.D. in physics from Osaka University in 1959. Since then, he has joined Osaka University, Sony Corporation Research Laboratory, Centre d'Etudes Nucléaires de Saclay, University of Tokyo (Institute for Solid State Physics), Yamaguchi University, and Hiroshima Institute of Technology. He is now Professor emeritus at the University of Tokyo. His current area of interest are light-induced phenomena and the electronic states of defects in amorphous and microcrystalline silicon.

Hadis Morkoç

Chapter D.32

Virginia Commonwealth University
Department of Electrical
and Computer Engineering
Richmond, VA, USA
hmorkoc@vcu.edu

Professor Hadis Morkoç received his Ph.D. from Cornell University, and is currently the Founders Professor of Electrical Engineering and Physics at the Commonwealth Virginia University in Richmond, Virginia, where his research interest cover GaN and related III–nitride semiconductors, ZnO and perovskite oxides, and quantum wells and quantum-dot structures. Professor Morkoç has authored and coauthored a number of books on optoelectronic materials and devices, such as *Nitride Semiconductors and Devices*, *Advanced Semiconductor and Organic Nano-Techniques*, *Principles and Technology of MODFETS*. He has published some 1300 technical articles in electronic and optoelectronic materials and devices from fundamental materials issues to device applications. Professor Morkoç is a Fellow of IEEE, Fellow of American Association for the Advancement of Science and a Life Fellow of the American Physics Society.

**Winfried Mönch**

Chapter A.8

Universität Duisburg–Essen
Duisburg, Germany
w.moench@uni-duisburg.de

Winfried Mönch received a Dr. rer. nat. degree from the Universität Göttingen in 1961. He spent three years at the AEG-Forschungsinstitut before joining the RWTH Aachen. There he qualified as university lecturer in 1968 and became Associate Professor two years later. In 1974 he was appointed Professor at the Universität Duisburg and retired in 1999. He was Walter Schottky Visiting Professor at Stanford University in 1981 and received the E. W. Müller Award 1984 of the University of Wisconsin–Milwaukee. He has authored two monographs on semiconductor surfaces and interfaces.

Arokia Nathan

University of Waterloo
Department of Electrical
and Computer Engineering
Waterloo, Ontario, Canada
anathan@uwaterloo.ca

Chapter [E.47](#)

Arokia Nathan is a Professor in Electrical and Computer Engineering at the University of Waterloo, Canada. He held the DALSA/Natural Sciences and Engineering Research Council of Canada (NSERC) industrial research chair in sensor technology, and was a recipient of the 2001 NSERC E. W. R. Steacie Fellowship. He currently holds the Canada Research Chair in Nanoscale Elastic Circuits. His research interests lie in materials devices, and circuits pertinent to large-area electronics.

Gertrude F. Neumark

Columbia University
Department of Applied Physics and
Applied Mathematics
New York, NY, USA
gfn1@columbia.edu

Chapter [D.35](#)

Gertrude F. Neumark is Howe Professor of Materials Science. Current research interests are electrical and optical properties of wide bandgap semiconductors, mainly ZnSe and III–nitrides. She is Fellow of the American Physical Society and has a listing by the American Physical Society on the archival web site for Notable Women in Physics. She was awarded by the National Science Foundation (NSF) as Visiting Professor at Columbia University (1982/83), and is Panelist for the National Research Council (NRC) and NSF.

Stephen K. O’Leary

University of Regina
Faculty of Engineering
Regina, SK, Canada
stephen.oleary@uregina.ca

Chapters [A.3](#), [D.33](#)

Stephen K. O’Leary is currently an Associate Professor in the Faculty of Engineering at the University of Regina. Professor O’Leary’s research focuses on novel electronic materials and the electron devices that use such materials. He is currently a member of the Institute of Electrical and Electronics Engineers and the Materials Research Society.

Chisato Ogihara

Yamaguchi University
Department of Applied Science
Ube, Japan
ogihara@yamaguchi-u.ac.jp

Chapter [C.25](#)

Dr. C. Ogihara received his Ph.D. degree in physics from University of Tokyo in 1988. He joined the University of Strathclyde in 1989, Gifu University in 1991 and Yamaguchi University in 1993. His current research focuses on photoluminescence and light-induced creation of defects in hydrogenated amorphous silicon.

Fabien Pascal

Université Montpellier 2/CEM2–cc084
Centre d’Electronique
et de Microoptoelectronique de
Montpellier
Montpellier, France
pascal@cem2.univ-montp2.fr

Chapter [B.20](#)

Fabien Pascal is involved in a research group working in electronic devices (MOS, MODFET, MESFET, TBH Si–Ge, TBH III–V) by means of their proper background I – V / C – V characteristics and noise spectral analysis. He is also working on the technological qualification of contacts, semiconductor materials and carbon nanotubes based devices by the use of noise spectroscopy. He is author and co-author of more than 70 publications in international journals and conferences.

Michael Petty

University of Durham
Department School of Engineering
Durham, UK
m.c.petty@durham.ac.uk

Chapter [E.53](#)

Michael Petty obtained his Ph.D. from Imperial College, London for work on semiconducting II–VI thin films. His current research activities encompass nanoscale architectures of organic materials, e.g. build up by techniques such as Langmuir–Blodgett deposition, self-assembly, and thermal evaporation. He has a special interest in the application of such thin layers to electronic and optoelectronic devices. He is currently Co-Director of the Durham Centre for Molecular and Nanoscale Electronics.

Asim Kumar Ray

Queen Mary, University of London
Department of Materials
London, UK
a.k.ray@qmul.ac.uk

Chapter E.54

Asim K. Ray B.Sc., M.Sc., Ph.D., D.Sc, FRSA holds the Chair in Functional Materials at Queen Mary, University of London. His research interests lie in thin-film technologies for fabrication of nanostructures and chemical and biosensors. He is a fellow of the Institution of Electrical Engineers, UK and the Institute of Physics (UK). He is a college member of the Engineering and Physical Science Research Council, UK and an honorary editor of the Proc. IEE – Circuits, Devices, and Systems.

John Rowlands

University of Toronto
Department of Medical Biophysics
Sunnybrook and Women's College
Health Sciences Centre
Toronto, Canada
john.rowlands@sri.utoronto.ca

Chapter E.48

John Rowlands is a Professor of Medical Biophysics at the University of Toronto. His research laboratories devoted to the study of X-ray imaging and positron emission tomography are located in the Research Institute of Sunnybrook and Women's Health Sciences Centre. His research interests are the fundamental limitations of image quality in radiation imaging.

Oleg Rubel

Philipps University Marburg
Department of Physics
and Material Sciences Center
Marburg, Germany
oleg.rubel@physik.uni-marburg.de

Chapter A.9

Dr. Oleg Rubel received his Ph.D. in material sciences from the Zaporozhye National Technical University in Ukraine in 2001. Since 2003 he has been working as a member of the Central Technological Laboratory and of the Semiconductor Theory Group at the Philipps University Marburg. His current research activities include theoretical aspects of transport and optical properties of crystalline, amorphous and organic semiconductors where carrier localization plays a dominant role, as well as atomic-scale characterization techniques for semiconductor heterostructures.

Harry Ruda

University of Toronto
Materials Science and Engineering,
Electrical and Computer Engineering
Toronto, Canada
ruda@ecf.utoronto.ca

Chapters A.2, A.3, D.41

Professor Harry Ruda received his Ph.D. from MIT in 1982 in Materials Physics, and worked as an IBM postdoctoral fellow from 1982 to 1984, developing one of first theories for electron transport in selectively doped heterostructures. From 1984 to 1989 he was a senior scientist at 3M Corporation, developed some of first models for electronic transport and optical properties of wide-band-gap II–VI semiconductors. Currently he is a full professor and chair in nanotechnology at the University of Toronto, and Director of the Centre for Nanotechnology. He has published over 170 papers in international refereed journals and holds 14 patents. His current research focuses on the fabrication and modeling of quantum functional nanostructures with applications in the fields of nanoelectronics and nanophotonics.

Edward Sargent

University of Toronto
Department of Electrical
and Computer Engineering
Toronto, Canada
ted.sargent@utoronto.ca

Chapter D.45

Ted Sargent is 2004-5 Visiting Professor, Nanotechnology and Photonics, in the Microphotonics Center at MIT. In 2003 he was named one of the world's top young innovators by MIT's Technology Review. In 2002 he was honoured by the Canadian Institute for Advanced Research as one of Canada's top 20 researchers under the age of 40. In his research he innovates devices for networking, energy, and medicine by applying colloidal quantum dots, photonic crystals, and other advanced nanomaterials.

Peyman Servati

Chapter E.47

Ignis Innovation Inc.
Waterloo, Ontario, Canada
pservati@uwaterloo.ca

Peyman Servati received the B.Sc. degree from the University of Tehran in 1998, and his M.A.Sc. and Ph.D. degrees from the University of Waterloo, Ontario, Canada, in 2000 and 2004, respectively. His present research interest lies in disordered organic and silicon thin-film transistors (TFTs) and nanostructured materials. He was a recipient of the 2005 NSERC Doctoral Prize, NSERC Postgraduate Scholarship, and the Bronze Medal in the XXV I.Ph.O. competitions held in Beijing, China, 1994.

Derek Shaw

Chapter A.6

Hull University
Hull, UK
DerekShaw1@compuserve.com

Dr. Derek Shaw received his B.Sc. in physics from the University of Manchester in 1950 and his Ph.D. in meteorology from Imperial College London in 1955. After spending several years in industry working on thermionic emitters and photoconductors he joined the Physics Department of Hull University in 1963. There he initiated research in semiconductor diffusion with specific interest in Si, Ge, AlSb, GaAs, GaSb, CdTe, CdS, HgCdTe and PbSnTe. In retirement his interest in HgCdTe continues in collaboration with SELEX Sensors & Airborne Systems.

Fumio Shimura

Chapter B.13

Shizuoka Institute of Science and Technology
Department of Materials and Life Science
Fukuroi, Shizuoka, Japan
shimura@ms.sist.ac.jp

Dr. Shimura has been engaged in both fundamental and practical science and engineering related to semiconductor crystal technology and semiconductor device processing, and is the author of *Semiconductor Silicon Crystal Technology*. Fumio Shimura received his Ph.D. degree in Applied Physics from Nagoya University, Japan in 1982. He is currently a professor at the Shizuoka Institute of Science and Technology and Adjunct Professor, North Carolina State University.

Michael Shur

Chapter D.33

Rensselaer Polytechnic Institute
Department of Electrical, Computer,
and Systems Engineering
Troy, NY, USA
shurm@rpi.edu

Dr. Shur is Patricia and Sheldon Roberts Professor, Professor of Physics, and Director of Broadband Center at RPI. He is fellow of the IEEE, APS, ECS, World Innovation Foundation, and a winner of van der Ziel Award and of several best conference paper awards. He holds over 30 patents on solid-state devices and was listed by the ISA as a highly quoted researcher.

Jai Singh

Chapter A.3

Charles Darwin University
School of Engineering and Logistics,
Faculty of Technology, B-41
Darwin, NT, Australia
jai.singh@cdu.edu.au

Jai Singh is Professor of Physics at the Charles Darwin University, Darwin, Australia and Fellow of the Australian Institute of Physics. He has held several visiting fellowships, including the Max Planck Institute (Germany), Visiting Professor (USA), JSPS Fellow (Japan), and Guest Professor (Denmark). His research interests are in condensed-matter theory, covering areas of excitonic processes in crystalline and amorphous semiconductors, nanostructures, and designing of solar cells. He has written two books, edited one book and four conference proceedings, and published 140 research papers.

Tim Smeeton

Chapter .1

Sharp Laboratories of Europe
Oxford, UK
tim.smeeton@sharp.co.uk

Tim Smeeton received his Ph.D. from the University of Cambridge in 2005 following research into the nanostructures of InGa_N quantum wells using transmission electron microscopy and X-ray scattering techniques. He is now with Sharp Laboratories of Europe, where he is researching group III–nitride quantum-dot structures and devices.

Boris Straumal

Russian Academy of Sciences
Institute of Solid State Physics
Chernogolovka, Russia
straumal@issp.ac.ru

Chapter C.24

Professor Straumal is Head of the Laboratory for Interfaces in Metals at the Institute for Solid-State Physics of the Russian Academy of Sciences at Chernogolovka, Russia, and a Full Professor at the Moscow State Institute of Steel and Alloys (Technological University) in the Faculty of Physical Chemistry. His research interests focus on grain boundaries, phase transformations, diffusion, thermodynamics, coating technologies, properties of coatings, crystal growth, and nanomaterials.

Stephen Sweeney

University of Surrey
Advanced Technology Institute
Guildford, Surrey, UK
s.sweeney@surrey.ac.uk

Chapter D.37

Stephen John Sweeney is a Senior Lecturer (Associate Professor) in Semiconductor Laser Physics at the Advanced Technology Institute, University of Surrey, UK. He holds a B.Sc. (hons.) in Physics and a Ph.D. in Semiconductor Laser Physics. His research interests are in low-dimensional semiconductors for use in lasers and other photonic devices with applications including communications, bio-sensing and solid-state lighting.

David Sykes

Loughborough Surface Analysis Ltd.
Loughborough, UK
d.e.sykes@lsaltd.co.uk

Chapter B.18

David Sykes graduated from the University of Warwick in 1970 with a B.Sc. in Physics and obtained his Ph.D. from the University of Aston in 1975. Following postdoctoral positions at the Universities of Birmingham and York he moved to Loughborough University in 1978 where he remained until setting up LSA Ltd. in 1997. He is Director of Loughborough Surface Analysis Ltd. in Loughborough, UK which provides responsive, confidential, professional contract surface analysis service to industry and universities. Presently he is Chairman of the UK Surface Analysis Forum (UKSAF), Vice Chairman of the British Vacuum Council (BVC), Chairman of the ISO Technical Committee 201 Subcommittee on Data Management and Treatment in Surface Chemical Analysis (ISO TC201SC3), and Recording Secretary of the International Union for Vacuum Science, Technique and Application (IUVSTA).

Keiji Tanaka

Hokkaido University
Department of Applied Physics,
Graduate School of Engineering
Sapporo, Japan
keiji@eng.hokudai.ac.jp

Chapter D.44

After graduating from a master course at Hokkaido University in 1972, Professor Keiji Tanaka worked on photoreceptors at Canon Co. Ltd. for two years. Then, coming back to the university, and he was promoted to a professor in 1991. He is also head of the research group on Photoelectronics in Disordered Materials of the Japan Society of Applied Physics. He is interested in the optoelectronic properties of amorphous materials, specifically chalcogenide glasses, and applications. He received the first Ovshinsky Award in 2001.

Charbel Tannous

Université de Bretagne Occidentale
LMB, CNRS FRE 2697
Brest Cedex, France
tannous@univ-brest.fr

Chapter A.4

Charbel Tannous holds a D.Sc. from Joseph Fourier University (Grenoble, France) and a Ph.D. from the University of Sherbrooke (Quebec, Canada). After being a Postdoctoral Fellow at Cornell University (Ithaca, USA), he joined the Department of Engineering Physics, Montreal, where he worked on $1/f$ noise in fractal circuits and microelectronic device simulation. Later he joined the AGT research and development department in Calgary as a Senior Researcher working on wireless communications and nonlinear signal processing. After being at TRLabs and simultaneously Associate Professor of Electrical Engineering at the University of Saskatchewan, he joined the Université de Bretagne Occidentale in Brest, France, as a Full Professor of Physics. Presently he is working on fast switching magnetization problems for high-density magnetic recording and giant magnetoresistance sensors.

Ali Teke

Balikesir University
Department of Physics, Faculty of Art
and Science
Balikesir, Turkey
ateke@balikesir.edu.tr

Chapter D.32

Ali Teke is currently an Associate Professor in the Physics Department at the Balikesir University, Turkey. He received his B.Sc. (1992) and Ph.D. (1997) degrees in the Physics Departments of the Middle East Technical University, Turkey and Essex University, UK, respectively. His current research activities include the investigation of the electronic and optical properties of wide-band-gap semiconductors such as GaN and ZnO and exploring new devices for electronic and optoelectronic applications. He has published more than 30 journal and conference papers and chapters in books.

Junji Tominaga

National Institute of Advanced Industrial
Science and Technology, AIST
Center for Applied Near-Field Optics
Research, CAN-FOR
Tsukuba, Japan
j-tomonaga@aist.go.jp

Chapter E.49

Junji Tominaga received his Ph.D. in Materials Science from Cranfield Institute of Technology, UK, in 1991. After completing his Ph.D., he was a senior member of research staff at TDK Corporation and developed optical phase-change materials for rewritable CD and DVD. He joined AIST in 1997. Now, he is Director of the Center for Applied Near-Field Optics Research, CAN-FOR, Japan. His current research interests are high-density optical data storage and nanophotonics in nanotechnology.

Dan Tonchev

University of Saskatchewan
Department of Electrical Engineering
Saskatoon, SK, Canada
dan.tonchev@usask.ca

Chapter B.19

Dan Tonchev is currently a Research Associate in Electronic and Photonic Materials in the Electrical Engineering Department at the University of Saskatchewan, Canada. He is also a Professor in Chemical Technology at the Plovdiv University in Bulgaria. He obtained his M.Sc. (1981) from the Moscow State University, and Ph.D. (1990) in materials engineering from the University of Chemical Technology and Metallurgy, Sofia, Bulgaria. His research interests are in the preparation and characterization of glasses and polymers. He has published more than 40 journal and conference papers and chapters in books, and has 14 patents (US and European). He is a member of the American Chemical Society.

Harry L. Tuller

Massachusetts Institute of Technology
Department of Materials Science
and Engineering, Crystal Physics
and Electroceramics Laboratory
Cambridge, MA, USA
tuller@mit.edu

Chapter A.11

Harry Tuller received his Eng.Sc.D. from Columbia University in 1973 and joined the MIT faculty in 1975. Current research focuses on functional materials/MEMS integration and solid-state ionic-device optimization. He is Fellow of the American Ceramic Society, a von Humboldt awardee and recipient of *docteur honoris causa* of the Université de Provence, Marseille, France. He co-founded Boston Microsystems and is a pioneer in micromachined SiC-based sensor arrays.

Qamar-ul Wahab

Linköping University
Department of Physics, Chemistry,
and Biology (IFM)
Linköping, Sweden
quw@ifm.liu.se

Chapter C.24

Qamar-ul Wahab has a Master and M.Phil. degree in Physics from Qaid-i-Azam University, Islamabad, Pakistan. He earned his PhD in 1994 from Linköping University, Sweden in the area of silicon carbide materials and devices. Currently he is working as an Associate Professor at IFM, Linköping University and Senior Researcher at Swedish Defence Research (FOI). He worked with ABB Corp. Res. from 1995–1998 in the SiC power-device program designing and fabricating 3 kV Schottky barrier diode in 4H-SiC. Current research interests are in modelling and simulations of microwave power transistors and amplifiers.

**Robert M. Wallace**

Chapter C.28

University of Texas at Dallas
Department of Electrical Engineering
Richardson, TX, USA
rmwallace@utdallas.edu

Robert M. Wallace earned his Ph.D. in Physics from the University of Pittsburgh in 1988. In 1990, Wallace joined Texas Instruments and was appointed (1997) to manage materials research on advanced device concepts and the associated integration issues. In 2003, he joined the University of Texas at Dallas as a Professor of Electrical Engineering and Physics. He has over 85 publications and 65 US and international patents.

**Jifeng Wang**

Chapters B.16, D.34

Tohoku University
Institute of Multidisciplinary Research
for Advanced Materials
Sendai, Japan
wang@tagen.tohoku.ac.jp

Jifeng Wang received his Ph.D. degree from the Chinese Academy of Sciences in 1992. After a postdoctoral fellowship at Nagaoka University of Technology he became an Assistant Professor at the same University. From 1995 until now he has been working at Tohoku University. His current research focuses on the growth of II–VI compound semiconductors and environmental semiconductors.

David S. Weiss

NexPress Solutions, Inc.
Rochester, NY, USA
David_Weiss@Nexpress.com

Chapter D.39

David S. Weiss is a Scientist Fellow at NexPress Solutions, Inc. (a Kodak Company), in Rochester, New York. He received his Ph.D. in chemistry from Columbia University, New York in 1969. His research interests focus on electrophotographic technologies with emphasis on organic photoreceptors. He holds 16 U.S. patents and is author on over 70 publications. He is co-author of *Organic Photoreceptors for Imaging Systems*.

Rainer Wesche

Swiss Federal Institute of Technology
Centre de Recherches
en Physique des Plasmas
Lausanne, Switzerland
rainer.wesche@psi.ch

Chapter E.52

Rainer Wesche studied physics at the University of Constance, Germany. After completing his diploma in 1984, he was assistant from 1985 to 1989 (Ph.D. in 1988). From 1989 to 1993 he was a research scientist at the Paul Scherrer Institute in Switzerland, where he led an experimental study of high-current applications of high- T_c superconductors funded by the Swiss National Science Foundation. Since 1994 he has been a research scientist at the Swiss Federal Institute of Technology Lausanne. His present research is in the field of applied superconductivity.

**Roger Whatmore**

Chapter C.27

Tyndall National Institute
Lee Maltings, Cork, Ireland
roger.whatmore@tyndall.ie

Roger Whatmore is Professor of Engineering Nanotechnology, researching the use of ferroelectrics in microsystems and nanotechnology. He has published over 200 papers and 30 patents in the field. He is a Nelson Gold Medal and Griffith Medal winner, a fellow of the Royal Academy of Engineering and a fellow of the Institute of Materials, Minerals and Mining.

**Neil White**

Chapter C.30

University of Southampton
School of Electronics
and Computer Science
Highfield, Southampton, UK
nmw@ecs.soton.ac.uk

Neil White is Professor of Intelligent Sensor Systems in the School of Electronics and Computer Science at the University of Southampton, UK. He is a fellow of the Institution of Electrical Engineers (IEE) and the Institute of Physics (IOP) as well as a Senior Member of the IEEE. Professor White has published extensively in the field of sensor technology and novel sensing materials.

Magnus Willander

University of Gothenburg
Department of Physics
Göteborg, Sweden
mwil@fy.chalmers.se

Chapter C.24

Magnus Willander is chaired professor in physics at Gothenburg University in Sweden. He did pioneering works on Si/SiGe heterojunction bipolar transistors (HBTs), polymer transistors, and laser transistors. His interest in soft materials in the last five to six years led to the demonstration of the water transistor and its applications. Professor Willander combines experimental and theoretical research.

Jan Willekens

University of Leuven
Laboratorium voor Halfgeleiderfysica
Leuven, Belgium
jan.willekens@kuleuven.ac.be

Chapter A.7

Jan Willekens studied Physics at the University of Leuven, Belgium, and is currently a Physics Tutor at the Faculty of Engineering of the same University. He is using steady-state and transient photoconductivity techniques to study photogeneration and electronic transport in disordered semiconductor structures with special emphasis on polymeric blends for photovoltaic applications.

Detailed Contents

List of Abbreviations	XXIX
------------------------------------	------

1 Perspectives on Electronic and Optoelectronic Materials	
<i>Tim Smeeton, Colin Humphreys</i>	3
1.1 The Early Years	4
1.2 The Silicon Age	4
1.2.1 The Transistor and Early Semiconductor Materials Development	4
1.2.2 The Integrated Circuit	6
1.3 The Compound Semiconductors	8
1.3.1 High Speed Electronics	9
1.3.2 Light Emitting Devices	10
1.3.3 The III-Nitrides	12
1.4 From Faraday to Today	14
References	14

Part A Fundamental Properties

2 Electrical Conduction in Metals and Semiconductors	
<i>Safa Kasap, Cyril Koughia, Harry Ruda, Robert Johanson</i>	19
2.1 Fundamentals: Drift Velocity, Mobility and Conductivity	20
2.2 Matthiessen's Rule	22
2.3 Resistivity of Metals	23
2.3.1 General Characteristics	23
2.3.2 Fermi Electrons	25
2.4 Solid Solutions and Nordheim's Rule	26
2.5 Carrier Scattering in Semiconductors	28
2.6 The Boltzmann Transport Equation	29
2.7 Resistivity of Thin Polycrystalline Films	30
2.8 Inhomogeneous Media. Effective Media Approximation	32
2.9 The Hall Effect	35
2.10 High Electric Field Transport	37
2.11 Avalanche	38
2.12 Two-Dimensional Electron Gas	39
2.13 One Dimensional Conductance	41
2.14 The Quantum Hall Effect	42
References	44

3	Optical Properties of Electronic Materials: Fundamentals and Characterization	
	<i>Safa Kasap, Cyril Koughia, Jai Singh, Harry Ruda, Stephen K. O'Leary</i>	47
3.1	Optical Constants	47
3.1.1	Refractive Index and Extinction Coefficient	47
3.1.2	Kramers–Kronig Relations	49

Glossary of Defining Terms 1333

Subject Index 1367

Glossary of Defining Terms

π Band

Equivalent of the valence band in an organic semiconductive material

σ Bond

Bond formed along the internuclear axis, between the nuclei of the atoms. In ethylene, a σ bond is formed by the overlap of two carbon sp^2 hybrid orbitals

π Bond

Chemical bond formed between the nuclei of atoms. There are two bonding regions above and below a nodal plane containing the nuclei. In ethylene, a π -bond is formed by the overlap of p orbitals on the carbon atoms

π^* Band

Equivalent of the conduction band in an organic semiconductive material

A

Abbe Number

(v_d) a measure of the dispersion (wavelength dependence) of the refractive index n of transparent materials at visible wavelengths.

$v_d = (n_d - 1)/(n_F - n_C)$, where $d = 587$ nm, $F = 486$ nm, and $C = 656$ nm. Typically v_d takes values of 80–20, which decreases with increasing n_d from 1.5 to 1.9

Absorption Coefficient

(α) The absorption coefficient represents the logarithmic decrement of the incident light intensity per unit length in the material

Acceptor

Impurity in a semiconductor or any other electroluminescent device capable of inducing hole conduction and accepting a valence-band electron to produce an acceptor energy level

Acceptor Level

A level with energy E_a that acquires electron captured from the valence band to an orbit near the acceptor's atom

Acceptor Concentration

Number of acceptors cm^{-3} . It refers to the total concentration N_a and the concentration of ionized acceptors N_a^-

Accumulation

The condition in which, for an MIS structure, the applied voltage to the gate electrode V_G results in an increase in the density of majority carriers near the surface of the underlying semiconductor. The applied voltage is less than the flatband voltage, $V_G < V_{FB}$

ACRT

Accelerated crucible rotation technique: a means to stir liquids in sealed ampoules, leading to improvements in crystal properties

Active Material

The main functional component of the thick-film paste, usually in the form of a finely divided powder

Active Matrix Addressing

The technique used to write and change images on complex liquid-crystal displays. Each display consists of thousands of picture elements (pixels) arranged as a matrix of columns and rows. Each pixel has a transistor switch [thin-film transistor (TFT)], which has been deposited onto one plate of the liquid-crystal display. A voltage is applied sequentially to the rows of pixels, and selected pixels within each row are switched on by data voltages on the columns. As the next row in the sequence is activated, the elements of the previous row are switched off from the data line by the TFT, but hold their charge as an electrical capacitor until the row is addressed next time in the sequence, after a full frame time. Thus the image is built up line by line, and individual pixels must hold their charge for the period of the full frame-address time

Air Mass Number

This is often abbreviated to AM followed by a number and characterizes the intensity and spectrum of light (modified by absorption in the atmosphere). The AM number is 0 for no air mass (i. e. for a satellite solar array), 1 for the sun directly overhead and 1.5 for the sun at 45° to the horizon

All-Optical Switch

Optical inputs are switched by other optical signals. The switching is produced in many cases by refractive-index changes. Comparing electronic devices such as transistors, in which an electrical input is controlled by an electrical current, we expect that the all-optical switch can work faster, being free from electrical noises. However, at present, in contrast to the μm scale of a transistor, an all-optical switch may have cm scales

Amorphous Metaloxides

Glassy alloys of a transition metal with oxygen, typical examples being TiO_2 , Ta_2O_5 , Nb_2O_5 , and Y_2O_3 . In bulk form, these materials are typically polycrystalline or crystalline ceramics. However, amorphous thin films can be deposited with relative ease, and they have been widely used as high-index layers in optical filter design and as dielectric layers in the microelectronics industry

Amorphous Network

Network consisting of atoms distributed randomly with a short-range order, i. e., holding a regular coordination of atoms

Amorphous Semiconductors

Semiconducting materials having a random network without long-range order

Amorphous Silicon

Thin films of silicon with a structure that is noncrystalline but which have the advantage of a higher absorption coefficient compared to crystalline silicon

Amphiphilic

An organic molecule possessing both polar (hydrophilic) and nonpolar (hydrophobic) chemical groups. The classic examples are fatty acids, which consist of a nonpolar ($-\text{CH}_2-$) chain terminating in a polar $-\text{COOH}$ acid group

Amphoteric Dopants

Dopants that may serve both as acceptors and donors

Amphotericity

This occurs when an impurity can act either as an acceptor or a donor. In GaAs, a Si atom can take up a site on either sublattice and can act as a shallow donor or shallow acceptor

Analytical Electron Microscopy

The application of transmission and/or scanning electron microscopy for the purpose of structural and/or chemical microanalysis

Anion

The electronegative atomic component in a compound, e.g. As in GaAs, Se in ZnSe

Annealing

Low-temperature heat treatment, normally in the presence of Hg, with the aim of adjusting the electrical properties of materials. The process of heating and slowly cooling semiconductor materials to reverse lattice damage. As a metallurgical term annealing describes the use of heat to reduce the internal energy of a crystal. This energy may be mechanical (strain) or may represent variations in concentration, which can be reduced by diffusion, etc.

Antiferromagnetically Coupled Media (AFM)

See synthetic ferrimagnetic media (SFM)

Anti-site Defect

Occurs in semiconductor compounds and is an anion (cation) replacing a cation (anion) on a regular cation (anion) lattice site e.g. As_{Ga} (Ga_{As}). The anion As_{Ga} (cation Ga_{As}) anti-site is expected to be a donor (acceptor) in the III–Vs and similarly in the II–VIs

Apparent Bandgap Narrowing

Definition of apparent bandgap seen in bipolar transistors due to the combined effects of bandgap narrowing due to heavy doping and the use of Fermi–Dirac statistics

Areal Density

Number of bits per unit area stored on a recording medium. In disk drives, it is the product of the bits/unit length times the number of tracks per unit length (usually inches and the areal density is frequently quoted in Gbits/in²)

Arrhenius Relation

A general expression connecting the value of a parameter in a thermally activated process to the absolute temperature T . So a diffusivity $D = D_0 \exp(-Q/k_B T)$ where D_0 , Q and k_B are the pre-exponential factor, the activation energy for diffusion and Boltzmann's constant, respectively

Astigmatism

A defect in the performance of a lens arising from the lens asymmetry about the optic axis, leading to loss of sharpness of an image at focus

A-Swirl

A network of dislocations loops. The origin is a stacking fault of Si interstitials. The size of the dislocation loops can be many μm

Attenuated Total Reflection (ATR)

Technique to measure infrared absorption spectra of thin films on a prism with enhanced sensitivity utilizing multiple reflections of an infrared beam in the prism

Auger Electron Spectroscopy (AES)

A method in which an electron spectrometer is used to measure the energy distribution of Auger electrons emitted from a surface

Auto-compensation

Often associated with amphotericity, auto-compensation occurs when the incorporation of electrically active impurities of one type leads to the automatic incorporation of electrically active defects of the opposite type. As an example, the doping of melt-grown GaAs with donors always leads to inadvertent incorporation of acceptors at about one tenth of the donor concentration

B

Back End of Line (BEOL)

A term generally describing the final points in the IC fabrication process line, such as the interconnection and packaging fabrication steps. These process steps generally require lower thermal budgets

Backscattered Electrons

Incident electrons that have interacted with atomic nuclei and scattered backwards with comparable incident energy. They may be used for sample imaging with contrast dependent on the local averaged atomic number

Baldereschi Concept

Mean-value k -points in the Brillouin zone are defined such that the value that any given periodic function of

the wavevector assumes at these special k -points is an excellent approximation to the average value of the same function throughout the Brillouin zone

Band Offset

The valence- and conduction-band offsets describe the corresponding band-edge discontinuities at intimate and abrupt semiconductor–semiconductor interfaces

Band Alignment

Type I: electrons and holes are confined within the same layer. Type II: electrons and holes are confined in different (adjacent) layers

Band Filling

An effect that takes place when a semiconductor is illuminated with light at a frequency within the absorbing region. Upon absorption of the incident photons, the electrons undergo a transition from an occupied band (VB) to the empty band (CB), thereby partially populating the empty band

Bandgap (BG), Band Gap or Energy Gap

The forbidden energy gap between the valence band, normally filled with electrons, and the conduction band, normally empty of electrons. The bandgap energy measures the energy difference between the top of the valence band and the bottom of the conduction band. The *optical BG* is the photon energy above which semiconductor absorbs energy of incident EM radiation. It may be direct or indirect, depending on type of electron transition from VB to CB the radiation induces; in Si, the optical BG is indirect with $E_g = 1.17$ eV at 4.2 K

Bandgap Engineering

The science of tailoring the semiconductor band gap to control the electrical and optical properties of the material

Barrier Height

The barrier height of a Schottky contact is the energy distance right at the metal–semiconductor interface from the Fermi level to the majority-carrier band-edge, i. e., the conduction-band maximum in n-type and the valence-band maximum in p-type contacts

Beam Effective Pressure Ratio

In molecular beam epitaxy, this is the ratio between the partial pressures of the various components of the molecular source beams

BEEEM (Ballistic-Electron-Emission Spectroscopy) Technique

A method to determine the barrier heights of Schottky contacts by tunnel injection of almost monoenergetic electrons from a biased metal tip into metal–semiconductor contacts that pass the metal films as ballistic electrons and are collected by the semiconductors, provided their energy is high enough to overcome the interfacial barriers

Birefringent Crystals

Crystals such as calcite that are optically anisotropic, which leads to an incident light beam becoming

separated into ordinary (o-) and extraordinary (e-) waves with orthogonal polarizations; incident light becomes doubly refracted because these two waves experience different refractive indices n_o and n_e

BLIP

Abbreviation for background-limited performance, which describes the best signal-to-noise performance that can be achieved with a detector. In this condition the only noise stems from the random arrival rate of photons and is therefore at a theoretical minimum

Blocking Temperature

Temperature where the magnetic exchange coupling between an antiferromagnet and a ferromagnet vanishes

Boltzmann Equation (BE)

Generally an integro-differential equation that governs the carriers' distribution function. At equilibrium the BE is automatically satisfied by a Fermi distribution. The generalized BE is a version revised to include quantum effects in the carrier's scattering and interaction with EM fields. Methods for the solution of the BE include the relaxation time, variational, displaced Maxwellian and Monte Carlo methods

Boule

There are many terms used for large crystals. These include boule, ingot and crystal. The top of the crystal is called the seed end, the first to solidify, etc. The bottom is called the tail or tang end

Bragg's Law

Can be summarized by the defining equation $\lambda = 2d_{hkl} \sin \theta$, which must be satisfied for constructive interference to occur, corresponding to maxima in the positions of diffracted intensity

Bravais Lattice

A repetitive arrangement of points in space such that the environment of each point is identically similar to that of every other point. 14 such arrangements are used to describe crystal systems

Bremsstrahlung

Electromagnetic radiation produced by the rapid deceleration of an electron in the vicinity of an atomic nucleus

Bridgman Growth (Technique)

Technique developed in order to grow compounds where one component is volatile at the growth temperature. The growth is carried out by physically withdrawing the melt from its furnace, while the melt crystallizes on a seed. The volatile component is replenished from a reservoir in a separate furnace. The arrangement of the equipment can be horizontal or vertical, the former offering the possibility of viewing the top of the solid/liquid interface and giving visual feedback of the growth process

Brillouin Zone (BZ)

A primitive cell in the reciprocal-space lattice, which proves to be body-centered cubic (BCC) for Si. The

BZ provides the domain of wavevectors k , which relate to the electron momentum in crystal $p = \hbar k$.

Broadband Sensitizer

Typically a species that is co-doped along with rare-earth ions into a glass host to increase the pumping efficiency or radiative efficiency of the rare-earth ions. Various sensitizers have been demonstrated, including silicon nanoclusters, silver ions, and other rare-earth ions (such as in the sensitization of erbium by ytterbium)

Brooks–Herring (BH) Formula

Celebrated equation for the carrier's momentum relaxation time due to scattering by ionized impurities

Bulk Modulus

Ratio of the compressive or tensile force applied to a substance per unit surface area to the change in volume of the substance per unit volume

C

C/V Technique (Capacitance–Voltage Technique)

The C/V technique is a method to determine barrier heights of Schottky contacts from the variation of their capacitance as a function of applied voltage

Calamitic

Denotes the rod-like shape of the molecules forming the majority of liquid-crystal phases that, therefore, are known as calamitic liquid crystals

Capacitance Equivalent Thickness (CET)

Theoretical thickness of SiO₂ that would be required to achieve the same capacitance density as an alternative dielectric material. This is extracted directly from, for example, the accumulation region of a C–V curve and has no further correction

Capacitance–Voltage (C–V)

C–V measurements of a MOS capacitor can be used to determine the oxide thickness and the amount of electrically active defects (fixed charge, trapped charge, mobile charge, and interface trapped charge) and mobile contaminants in the oxide. It can also be used to determine the oxide thickness and the profile of dopants at the semiconductor surface. It is a common characterization technique used in wafer fabrication facilities

Carrier Mobility

Measure of the effect of applying an electric field to charge carriers (electrons or holes). It is the additional velocity acquired by the carriers (drift velocity) divided by the electric field

Carrier Range

Determines how far an injected carrier moves per unit field before becoming immobilized in a deep trap. Sometimes, it is calculated as the product of the drift mobility and lifetime

Carrier Concentration

Number of the current carriers per cm^{−3}. It can be

electron concentration n and/or holes concentration p . The intrinsic carrier concentration (n_i) is $n = p$ in a perfect crystal semiconductor that has not been doped (i. e., an intrinsic semiconductor). The value of n_i for Si is approximately to 1.08×10^{10} cm^{−3} at 300 K

Carrier Velocity, Microscopic

Gradient of specific band spectrum $E_s(k)$ with respect to p

Cascaded Second-Order Materials

Materials that exhibit second-order nonlinear properties that act as an effective third-order nonlinear material

Cathodoluminescence

Luminescence stimulated by energetic electrons

Cation

Electropositive atomic component in a compound, e.g. Ga in GaAs, Cd in CdS

Cd-Based Compound Semiconductor

Semiconductor that contains the element Cd

Centro-symmetric

A crystal structure in which a center of inversion exists is called centro-symmetric. There are 32 crystal classes, among which 11 are centro-symmetric

Cermets

Standard form of thick films requiring exposure to a high-temperature firing cycle, typically in the range 700–1000 °C

Chalcogenide Glasses

Glasses that are amorphous alloys containing S, Se, and/or Te. Typical examples include Se, GeS₂, GeSe₂, As₂S₃, As₂Se₃, and As₂Te₃. By intermixing these and other binary chalcogenide glasses, a wide variety of multicomponent glasses can be formed. Further, a wide range of nonstoichiometric compositions is possible. Several compositions have become standard industrial materials, including Ge₃₃As₁₂Se₅₅ and Ge₂₈Sb₁₂Se₆₀. The chalcogenide glasses are characterized by narrow bandgaps and good transparency in the mid- to far-infrared wavelength range

Characteristic X-Ray

An X-ray photon generated by the transition of an outer-shell electron to an inner-shell vacancy of an atom, with energy characteristic of the element

Charge-Blocking Layer

A layer that is sometimes placed between the conductive layer and the subsequently coated layer (usually the *charge-generation layer*) to prevent charge injection in the dark

Charge Carriers

Generally current-carrying (free) electrons and holes in conduction and valence bands, respectively, and electrons trapped by nearby impurity atoms

Charge Generation

Conversion of absorbed light into charges that are injected into, and subsequently transported through,

the *charge-transport layer* of an organic photoconductor

Charge-Generation Layer (CGL)

A layer in an organic photoconductor in which light is absorbed and converted into electrically charged species

Charge-Generation Material (CGM)

The light-absorbing material in the *charge-generation layer*

Charge Pumping

Electrical technique used to determine the interface state density in MOSFETs. In its simplest implementation, voltage pulses of well-defined properties of amplitude, rise and fall times and period are applied to the gate terminal of a MOSFET with the source and drain terminals grounded, and the substrate current is measured as the base level of the gate pulse is swept from below accumulation to above threshold voltage. The resulting substrate current is then used to extract the interface trap charge density (cm^{-3})

Charge Transport

involves electron hopping through a polymer matrix containing charge-transport moieties (see MDP). The charge carrier for hole transport is the radical cation and that for electron transport is the radical anion of the charge-transport moiety

Charge-Transport Layer (CTL)

The layer in an organic photoconductor through which charges generated in the CGL are transported

Charge-Transport Material (CTM)

The *charge-transport layer* dopant that transports charge injected from the *charge-generation material*

Chemical Annealing

A concept to explain crystal formation by the assistance of chemical species such as atomic hydrogen during film growth

Chemical Vapor Deposition (CVD)

Technique for the growth of thin solid films on a crystalline substrate as the result of thermochemical vapor-phase reactions. This reaction occurs above a solid surface, e.g. a diamond single crystal, which causes deposition onto that surface. In the CVD technique the thin films are obtained under equilibrium conditions. The gas-phase reaction is activated by temperature in order to create condensable species that lead to film growth. Different CVD techniques have been developed (See: *Mercury-sensitized photo-CVD*, *Hot-wire CVD*, *MOCVD*, *MPCVD*, *PECVD*). All techniques used for the production of diamond require a means of activating gas-phase carbon-containing precursor molecules, usually CH_4 , diluted by hydrogen

Chiral Nematic

Liquid-crystal phase in which the director is twisted into a helical arrangement; the phase is, therefore, not

superimposable on its mirror image and so exhibits macroscopic chirality. The chirality of the phase originates from that of the constituent molecules. The chiral nematic is sometimes referred to as a cholesteric phase

Chromatic Aberration

A blurring of resolution due to the differing focal lengths of a lens when acting on electrons of differing energy

Cleave and Stain

This is a rapid, though destructive, technique for assessing semiconductor structures. Particular chemical mixtures affect the surfaces of different semiconductor types in different ways, giving rise to effects that can be seen in a simple optical microscope. The sample is first cleaved to produce a clean surface, preferably at an angle that tends to magnify the scale of the structure, and then stained

CMT

A narrow-bandgap II–VI semiconductor compound, $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$, which is still the preeminent infrared (IR) material

Coefficient of Thermal Expansion (CTE)

Increase in the length of a macroscopic material for a given temperature increase. The units of CTE are $1/^\circ\text{C}$

Coercive Field

The electric field required to reduce the polarization in a ferroelectric material to zero in a fully saturated ferroelectric hysteresis loop

Coercive Squareness Parameter (S^*)

The slope of the major hysteresis curve of a ferromagnetic recording layer normalized to the ratio of the remanent magnetization to the coercive field $S^* = 1 - [M_r/H_c / dM/dH(H = -H_c)]$

Coherence Length

ξ is the shortest distance within which a considerable change of the Cooper-pair density is possible

Cohesive Energy

The energy required to dissociate the atoms of a solid into isolated atomic constituents

Columnar Phase

A liquid-crystal phase in which the constituent molecules, usually disc-like, are stacked into columns; these are arranged parallel to each other in either a hexagonal or rectangular array

Complementary Metal Oxide Semiconductor (CMOS)

An MOS device technology consisting of nMOS and pMOS transistor pairs

Complex

A bound state between two or more adjacent, like or unlike species, e.g. an anti-site and a lattice vacancy at a nearest-neighbor site on the same sublattice such as $\text{As}_{\text{Ga}}\text{V}_{\text{Ga}}$

Compositional Uniformity

A critical parameter in all ternary alloy systems that

determines a material's usefulness in device applications

Compound Semiconductor

Semiconductor crystals composed of two or more atomic elements from different groups of the periodic chart

Compressive Strain

Type of strain obtained when a strained $\text{Si}_{1-x}\text{Ge}_x$ layer is grown on a silicon substrate

Compton Scattering

Transfer of energy from a photon to an electron, leading to the scattering of a longer-wavelength photon

Concentration Quenching

the reduction in luminescence efficiency and luminescence lifetime of a laser glass when the rare-earth dopant concentration is high. Quenching is due to interactions between closely spaced rare-earth ions at high concentrations. These interactions create new pathways, other than the desired radiative decay, for the ions to relax to the ground state after they have been raised to a desired lasing level by pump energy

Conduction Band (CB)

Band of energies allowed for electrons in a semiconductor, which is empty in undoped semiconductors. There are many CBs, separated by band gaps. However, CB term usually refers to the conduction band that has the lowest energies, or closest to the valence band (VB). It is separated from the VB by a band gap

Conductive Layer

The layer on which the *charge-generation layer* and *charge-transport layer* are coated. It is connected to ground in the electrophotographic process

Conductivity Mass

Used for electron or hole conductivity (mobility) calculation

Conductivity

Product of the number of electrons or holes per unit volume, the electronic charge and the mobility of the carrier $\sigma = ne\mu_{e,h}$

Configuration Coordinate Model

Model of interaction between electronic system of a luminescent center and the vibrational system of the surrounding atoms and ions

Converse Piezoelectric Effect

The generation of mechanical strain in a material in response to an applied electric field, where the strain is linearly proportional to the applied field

Conversion Efficiency

Ratio of incident photon energy and output electricity energy

Cooper Pairs

Bound electron pairs formed of electrons with opposite spins and momenta (in their ground state with zero electric field)

COP

A crystal-originated particle (COP) is a small aggregate or cluster of vacancies. Usually, it is of octahedral shape with (111) facets, but in the case of nitrogen doping, it can also adopt the form of a platelet or a rod-like cluster. The usual size is 70–200 nm

Corona Discharge

When a high voltage of 5–10 kV is applied to sharp edges or fine wires of metals, the gas such as air surrounding the metal is ionized and discharged. If the voltage is DC, ions having the same polarity with the DC voltage move toward a grounded electrode

Correlation Factor (f)

The jumps of a diffusing particle are generally not random but correlated, i. e. successive jumps are not independent of each other; f (always ≤ 1) is the ratio of the jump rate of correlated jumps to the jump rate if the jumps were random

Cotterell Atmosphere

The stress field around a dislocation can be reduced if defects congregate around them. This results in defect atmospheres, called Cotterell atmospheres, which are commonly observed even when the dislocation itself would not provide an observable signature. EL2 defects aggregate in this way in SI substrate material

Coupled Granular Continuous (CGC) Recording Media

In perpendicular recording media: a recording surface consisting of two layers: the first being granular and the second consisting of multilayers of typically cobalt and palladium

Critical (Transition) Temperature

The T_c is a characteristic property of the superconductor in question. At T_c the resistance drops abruptly to an unmeasurably small value

Critical Field

B_c is the magnetic field sufficient to destroy the superconducting state in a *type I superconductor*

Critical Fluctuations

Variations of the superconducting order parameter $\psi = n_C^{1/2} \exp(i\varphi)$ (where n_C is the Cooper-pair density) around the thermal equilibrium values

Critical Thickness

Maximum thickness of a strained layer that can be grown on a substrate before relaxation of the layer occurs

Cryopanel

Liquid-nitrogen-cooled surface within the growth chamber arranged to minimize contamination of the wafer surface by impurities

Current In the Plane (CIP)

Magnetoresistive device with the sense current flowing in the plane of the films

Current Perpendicular to the Plane (CPP)

Magnetoresistive device with the sense current flowing perpendicular to the plane of the films

CZ Crystals

Crystals grown according to the so-called *Czochralski technique*

Czochralski and Liquid-Encapsulated Czochralski (LEC) growth

Czochralski growth *pulls* a crystal from the melt. The seed is held in a holder vertically above the melt and rotated. After partial immersion into the melt, it is slowly withdrawn and the crystal forms on the seed. The growth takes place because of the increased heat loss from the crystal compared to the melt. Rotation of the seed and growing crystal leads naturally to a near-cylindrical crystal from which circular substrates can be sawn. The GaAs melt must be protected against As loss if this method is to be used. Boric oxide (see liquid encapsulation) liquifies on the surface of the melt and, to some extent, on the crystal and acts as a barrier against As loss. The boric oxide also insulates the melt from the crucible; reducing the rates at which impurities from the crucible are introduced into the melt and aiding withdrawal of the exhausted melt from the crucible after Growth

D**Dangling Bonds (Broken Bonds)**

Point-like defects that are produced by breaking covalent bonds. The dangling bond may have an unpaired electron, two paired electrons, or no electrons. These dangling bonds were denoted as D^0 , D^- , and D^+ by Mott, the superscript representing the charge state

Dark Decay

Rate of decrease of the surface potential of a charged organic photoconductor

Data Rate

Rate at which the digital data, recorded or read back in a digital storage device, is transferred. Characterized by Mbytes/s or MB/s, where a byte (B) is eight bits

Debye Length

A measure of the distance beyond which the electric field due to a point charge (e.g. an ionized dopant atom) is screened by the free carriers (electrons or holes) and becomes increasingly negligible

Deep-Energy-Level Impurities

Doping impurities or other impurities whose energy level lies toward the center of the bandgap

Deep-Level Transient Spectroscopy (DLTS)

DLTS is a useful technique for measuring concentrations of deep levels in conducting semiconductors. Deep levels within the depletion layer of a pn junction are filled by putting the junction into forward bias. On applying a reverse bias, these

levels are allowed to empty thermally. This produces a change in junction capacitance consisting of a series of exponentials. From the temperature spectra generated for different time windows of the transient, Arrhenius plots can be made to determine the energy level (eV) and capture cross section (cm^2) of the defects

Defect Chemistry

Representation of interactions between defect species and free carriers (dopant, impurity, native defect, electrons and holes) in terms of chemical-style equations from which the concentrations of the various species concerned can be obtained

Deformation Potential

Effective electric potential describing interaction of carriers with the lattice deformation irrespective of what is the cause of the deformation. It describes the phenomenology of the interaction between carriers and phonons of deformation types

Deformation Potential Parameters

There are two and four such parameters for electrons and holes in Si, respectively. For holes the parameter set includes one describing interaction with anti-phase deformation of atoms in the nonequivalent primitive cell's positions

Density of States

Widely abbreviated as DOS, the density of states is the number of energy states per unit energy interval at the energy E . It stands for the density distribution of allowed electronic energies in a material and is widely used with respect to this distribution across the bandgap of disordered semiconductors

Density-of-States Mass

Used for electron or hole density-of-states calculations

Depletion

The condition in which, for a MIS structure, the applied voltage to the gate V_G electrode results in a reduction of majority carriers near the surface of the underlying semiconductor. This region is referred to as the depletion layer. Charge remaining in this near-surface region is due to ionized dopants present in the channel region. This condition occurs for applied voltages between the flatband and threshold voltages, i. e. $V_{FB} < V_G < V_{thr}$

Depth of Field

The distance along an optic axis that an object can be moved without noticeably reducing the resolution

Depth of Focus

Maximum spacing between an imaging screen and a photographic plate (or CCD) that allows a recorded image to be retained in focus

Depth Profiling

Monitoring of signal intensity as a function of a variable that can be related to distance normal to the surface, cf. compositional depth profile. Note: the

signal intensity is usually measured as a function of sputtering time

Depth Resolution

Depth range over which a signal changes by a specified quantity when reconstructing the profile of an ideally sharp interface between two media or a delta layer in one medium

Detection Efficiency

Percentage of radiation incident on a detector system that is actually detected

Detective Quantum Efficiency (DQE)

The ratio of the square of the signal-to-noise ratio at the output of the detector to that at the input. The relative increase in image noise due to an imaging system as a function of the *spatial frequency*, f , is expressed quantitatively as $DQE(f)$, which represents the signal-to-noise transfer efficiency for different frequencies of information in an image

Detectivity

A signal-to-noise parameter, normalized to area and bandwidth, often used for photoconductive detectors or single-element photovoltaic detectors

Devitrification

The transition of a glassy material to its lower-energy crystalline state. This process is usually driven by thermal energy, such as if the material is held at some characteristic temperature above its glass-transition temperature. The difference between the crystallization temperature and the glass-transition temperature for a particular glass is one measure of its stability

DFT (Density-Functional Theory)

DFT is a quantum-mechanical approach to many-body electronic structure calculations of molecular and condensed-matter systems. The many-electron wave-function is written in terms of the electron density. The major problem with DFT is that the exact functionals for exchange and correlation are not known. The widespread approximations are the local-density approximation (LDA) and GW approximation (GWA). The LDA assumes the functionals for exchange and correlation to depend only on the density at the coordinate where the functional is evaluated. LDA DFT calculations dramatically underestimate the gaps of sp^3 -bonded semiconductors and insulators. In the GW approximation, the exchange and correlation is expressed as the product of a single-particle propagator G and a screened interaction W . GWA DFT calculations yield the gaps of sp^3 -bonded semiconductors and insulators generally to within a few tenths of an eV

Diamond Structure

A structure in which each atom lies at the center of a tetrahedron surrounded by four nearest neighbors located at the points of the tetrahedron. In such a structure diffusion is isotropic

Dielectric Constant/Susceptibility (DC/DS)

Basic material optical tensor property that linearly connects the electric displacement to the electric-field vector inside the material. For Si it is scalar. At optical frequency DC/DS is a complex quantity

Dielectric Materials

A class of materials that are insulators or nonconductors where charge imparted to one part of the material is not communicated to any other part

Diffraction

The process of scattering and reconstruction of radiation in specific directions as a consequence of interaction with a periodic structure, e.g. light interacting with a grating, or X-rays interacting with a crystal lattice

Diffusion Coefficient or Diffusivity

The macroscopic parameter that characterizes the jump rate or jump frequency of a species at the atomic level. It is normally obtained by matching experimental profiles to solutions of the appropriate diffusion equation, e.g. Fick's second law. The diffusion coefficient measurement techniques include Haynes–Shockley, time-of-flight and noise-measurement-based methods

Diffusion Length

Measure of the spatial extent of a diffusion region. Typically the concentration of a diffusant can be expected to fall by more than a factor of 10^3 over three diffusion lengths

Digital Printing

Technologies in which the image is comprised of a pattern of pixels. In electrophotographic digital printing the electrostatic latent image is written on a charged photoreceptor using a computer-controlled laser or LED bar

Dipping

Liquid-phase epitaxy technique in which the substrate is lowered into the melt in a vertical orientation

Direct Piezoelectric Effect

The generation of an electric polarization change or a charge separation in a material in response to an applied stress, where the polarization change is linearly proportional to the applied stress

Director

Symmetry axis for properties such as the refractive index or dielectric tensor of a liquid-crystal phase; at a molecular level it is commonly associated with the preferred orientation of the unique axis of the constituent molecules, either rod-like or disc-like

Disclotic

Indicates the disc-like shape of the anisotropic molecules that constitute a class of liquid-crystal phases known as disclotic liquid crystals

Disorder Model

Derived from Monte Carlo simulation studies, this

model describes electronic transport in random media in terms of disorder-induced fluctuations of both hopping site energy and relative orientation

Distribution Function

A function of p (impulse) and the carrier's coordinate, which obeys *Boltzmann's equation* and presents a semiclassical probability description of a carrier's statistics and dynamics. At equilibrium, it converts to the Fermi function over the carrier's energy, which in turn reduces to a Maxwell-Boltzmann distribution for lightly doped semiconductors

Donor

An impurity in a material that is capable of inducing electrical conduction in that material by transferring an electron to the conduction band. A donor's level is the energy E_d of an electron in an orbit near the donor atom. The donor concentration is the number of donors cm^{-3} , referring to either the total concentration N_d and the concentration of ionized donors N_d^+

Dopant

An atom from a different group of the periodic table from the host atom that substitutes for it. It can be a donor, acceptor or amphoteric and is deliberately incorporated to give n- or p-type conductivity

Doped Semiconductor

A semiconductor that contains donors and/or acceptors. *Lightly* and *moderately doped* semiconductors contain impurities with energy levels that are well separated from the CB and VB. *Heavily doped* semiconductors (n^+ - or p^+ -type) contain so many dopants that their energy levels merge with CB or/and VB, which leads to metallic conduction at low temperatures. For n-Si, the critical donor concentration of this, Mott's insulator-metal transition, proves to be about $3 \times 10^{18} \text{ cm}^{-3}$. Fermi-Dirac statistics must be used for carriers in n^+ - or p^+ -type semiconductor, but in n^+ - or p^+ -Si full degeneracy of carriers is met only well below room temperature

DRAM

Dynamic random-access memory

Drift Mobility

Velocity per unit of applied field imparted to a charge carrier by the electric field. In the presence of carrier traps it is reduced from the free-carrier velocity by the fraction of time a carrier spends in the trapping centers

Drude Formula

Phenomenological equation for the free-carrier contribution to the *dielectric constant/susceptibility*. It contains two parameters: the effective plasma frequency and the relaxation time

Drum Photoreceptors

Devices where the layers are coated sequentially on a metal drum substrate

Dual-Layer Organic Photoconductor

A photoconductor with an architecture where the

charge-generation and charge-transport functions are carried out in separate layers (see *charge-generation layer* and *charge-transport layer*, respectively)

Dynamic Coercivity

The change of coercivity of small ferromagnetic particles with switching time under thermal excitation

E

E' Center

A kind of unpaired-electron dangling bond in oxide glasses. In SiO_2 , an Si atom that is bonded to three O atoms may have one E' center. The center, which may be produced by radiation, gives ESR signals and optical absorption at $\hbar\omega \approx 6 \text{ eV}$

E Layer

Thin ferromagnetic cobalt alloy film added to one or two sides of the Ru layer in a synthetic ferrimagnetic media to increase the exchange coupling

Easy Axis

Direction in a ferromagnetic sample along which the magnetization is oriented in the absence of an external magnetic field. In thin films, the easy axis is the direction in a substrate surface along which the director tends to align; it is determined by the nature of the surface treatment

Edge-Defined Film-Growth Technique

Shaped crystals, including tubes, sheets, etc., are grown through a die placed on the melt surface

Effective Mass

Generally a set of parameters describing the dynamics of the current carriers, which may deviate drastically from the free-electron mass. For Si, it includes the effective mass tensor of electron in the CB (m_t , m_l , m_l) and the masses of heavy (m_1), light (m_2) of spin orbital split-off (m_3) holes in the VB. Generally, $m_{1,2}$ depend on the direction of hole's momentum.

Different averages over this direction define masses that enter the conductivity and the DOS

Einstein Relation

An equation connecting the mobility μ , (speed per unit electric field) of a charged particle to its diffusivity D . Specifically $\mu = qD/kT$, where q is the electric charge on the particle. This expression is only valid for nondegenerate material

EL(2)

Electron level number 2. The deep levels in most semiconductors were labeled according to their observation during DLTS measurements. EL levels are donors (they are neutral when they have their electron). HL levels are acceptors (they are neutral when they have their hole). EL2 is the most important deep donor level (actually, a double donor) and is either the As anti-site defect or contains the As anti-site as a component

Elastic Compliance Constant (C)

Defined from Hooke's law by $X = Ce$, where X is the stress and e is the strain. It has units of pressure

Elastic Deformation

Deformation of a body in which the applied stress is small enough that the object retains its original dimensions once the stress is released

Elastic Stiffness Constant (S)

Defined from Hooke's law by $e = SX$, where e is the strain and X is the stress. It has units of inverse pressure

Elasticity

A property of liquid crystals that causes the directors to be uniformly aligned parallel to each other. Deviations from this uniform ground state require the addition of elastic energy to the liquid crystal

Electrically Conductive Adhesives (ECA)

Composite materials consisting of a dielectric curable polymer and metallic conductive particles. The polymer is an adhesive material that chemically reacts with metals and other polymers to form a bond. The metallic particles in the ECA form a network in the cured joint that form an electrical conduction path

Electro-absorption

Generic term for all effects of changing the absorption coefficient upon applying strong electric field. For Si, the dominant is the change of the free carriers' absorption in IR

Electrochemical Potential

In semiconductors (*see Fermi level*)

Electron Affinity

The energy distance from the conduction-band minimum to the vacuum level at the semiconductor surface

Electron-Beam Lithography

Method for micro- and nanoscale fabrication where a pattern on a polymeric layer (resist) is exposed to electron irradiation

Electron

Elementary particle having a negative charge of 1.602×10^{-19} C and rest mass m_0 equal to 9.109×10^{-31} kg

Electron-Phonon Scattering

In Si, in addition to scattering by deformation phonons, scattering may also occur with short-wavelength (inter-valley) phonons

Electro-optic Effect

A change in refractive index upon application of a strong electric field. This is linked to electro-absorption through the Kramers–Kronig relation. It manifests itself as a change in *birefringence* in response to an applied electric field

Electrophotography

Printing technology in which charged marking particles are developed on an organic photoreceptor with an image pattern of surface charge, the

electrostatic latent image, and the subsequent transfer of these particles to a receiver

Electroplating

Process used to deposit a material on a conducting substrate in a chemical bath containing metal ions using electrical current

Eley–Rideal Reaction

A surface-reaction scheme in which an arriving chemical species react on the surface without any surface diffusion process. It is considered the counterpart of a Langmuir–Hinshelwood reaction

Ellipsometry

Method of defining the optical constants by measuring the ratio of reflectance for s- and p-polarized radiation, and the relative phase shift between the two, at large incidence angles

Emission Device

An emission device creates photons from extra electron–hole pairs through a process called radiative recombination. The electron–hole pairs are often created by forward-biasing a pn junction

Encapsulation

A dielectric polymer material that flows over and covers the electronic components in a package to provide mechanical and electrical protection to the packaged devices

Energy Gap

see Bandgap

Energy-Band Spectrum

Dispersion relation $E_s(\mathbf{k})$ of allowed electron energy to \mathbf{k} within the *Brillouin zone*. As a function of small deviation of \mathbf{k} from the extrema points of $E_s(\mathbf{k})$ it proves to be anisotropic parabolic for the conduction band and non-parabolic for valence band, forming ellipsoid valleys and warped spheres, respectively, in the *Brillouin zone*

Epitaxial Layer (or Epilayer)

Thin crystalline layer on a single-crystal substrate with orientation and lattice structure determined by the substrate crystallography

Epitaxy

(Greek; arrange upon). This is the growth of one crystal (the epitaxial layer) on the surface of another (the substrate) and where the orientation of the grown layer is the same as the substrate. If the layer is of the same material as the substrate, the growth is homoepitaxial. If the layer and substrate are different, the growth is heteroepitaxial. Usually, epitaxy can only be performed where there is close match between the lattice constants, although it is possible for a layer of quite different lattice constant to be grown if there is a change in crystal orientation between the layer and the substrate. The term epitaxy was introduced to describe the importance of having parallelism between two lattice planes with similar networks of closely similar spacing

Equivalent Oxide Thickness (EOT, t_{eq})

The theoretical thickness of SiO₂ that would be required to achieve the same capacitance density as an alternative dielectric material. This is often determined by quantum-mechanical modeling of the C - V curve for thin dielectric layers (where tunnelling effects result in substantial “leakage” current) and/or where poly-Si gate electrodes (resulting in depletion effects) are present

Etch Pit Density (EPD)

This is the usual way in which substrate suppliers quote dislocation densities. EPD is found by etching the surface in molten alkalis, like KOH, and viewing the resulting pitted surface under an optical microscope. Each pit represents a single dislocation ending at the surface

Ewald Sphere

Geometrical construction used to illustrate the relationship between a diffraction pattern and the reciprocal lattice of a diffracting crystal

Exchange Field (H_{ua})

Parameter characterizing the strength of the coupling of a ferromagnetic to an antiferromagnetic film. Measured in Oe or A/m

Exciton

An electron-hole pair, which behaves like a H atom, with a binding energy of 10–100 meV and lifetime of ≈ 1 ns. The wave-function, in principle, extends over the whole crystal

Exhaustion Concentration

$N = |N_d N_a|$ is the maximum attainable carrier concentration in a doped semiconductor

F**Fermi Level or Fermi Energy**

For a metal, the Fermi level is defined as that energy below which its one-electron levels are occupied and above which they are empty in the ground state, i. e., at zero temperature. In the context of semiconductors, the term Fermi level is a synonym for their *electrochemical potential*

Ferroelastic

A material that exhibits a phase transition from a non-strained to a strained state, generating a spontaneous strain at the transition, and in which the spontaneous strain can be switched between two or more stable states by the application of a stress

Ferroelectric Domains

Adjacent regions in a ferroelectric crystal that have their spontaneous polarization vectors inclined to one another

Ferroelectric Hysteresis

The loop that is produced when the polarization in a ferroelectric material is plotted as a function of applied electric field

Ferroelectric Relaxor

A ferroelectric that shows a broad peak in relative permittivity at the paraelectric-to-ferroelectric phase transition and in which the temperature of the peak is strongly dependent upon measuring frequency

Ferroelectric

A polar dielectric in which the polarization can be switched between two or more stable states by the application of an electric field

Fick's First Law of Diffusion

For diffusion parallel to the x -axis the diffusant flux (atoms per unit area per second) is equal to $-D\partial c/\partial x$ where c is the diffusant concentration which defines the diffusivity D

Fick's Second Law of Diffusion

Based on the first law, this law gives the rate of build up of the diffusant concentration at a given depth as $\partial c/\partial t = \partial(D\partial c/\partial x)/\partial x$

Field-Effect Transistor (FET)

A transistor where the current between two electrodes (the drain and source) is modulated by the electric field from a third electrode (the gate)

Field Emission

Electron emission from a metal or semiconductor into vacuum under the influence of a strong electric field

Figure-of-Merit (FOM)

Measure of the performance of an integrated circuit technology. The time delay associated with signal propagation is a common metric

Fill Factor (FF)

Measure of the maximum power that can be obtained from a photovoltaic solar cell compared with the product $I_{sc} \cdot V_{oc}$

Firing

One of the key stages of the thick-film production process. It is usually undertaken in a continuous-belt furnace at temperatures of up to 1000 °C

Flatband Voltage (V_{FB})

The voltage applied across an MIS device at which there exists no charge in the semiconductor. As a result, the valence and conduction band structure of the semiconductor is flat. This condition occurs when this voltage equals the workfunction difference between the metal electrode and the semiconductor under ideal conditions. The presence of charges in the insulator or at the interface, due to defects, modifies the voltage required to achieve the flatband condition

Flexoelectricity

Generation of a macroscopic electrical polarization in a nematic liquid crystal when the director distribution is deformed from its uniform state of alignment. The inverse of this effect is the deformation of the director distribution when an electric field is applied to a nematic; the magnitude of the deformation is linear in the field

Flip Chip

Integrated-circuit-level interconnect that can be used to replace wirebond interconnects. The flip chip is a solder bump on an area array on the chip surface that routes the power, ground and signals from the integrated circuit to the bumps. The metallization on the IC surface is called the under-bump metallurgy that forms a metallurgical bond with the solder. The flip-chip die is joined to the package by placing the die face down on the matching bond pads on a substrate and reflowing the solder to form an electrical, thermal and mechanical interconnect

Floating Gate Current

Very small gate currents (\approx fA or less) can be measured using the floating gate technique in which the drain current of a MOS transistor is measured after the gate bias has been removed. Then, by using the decay in the drain current as a function of time and the measured drain current versus gate voltage characteristics and the oxide capacitance, the gate current can be calculated

Floating Zone (FZ) Technique

This technique uses a solid feed rod that is melted at its lower end by a high-frequency coil. The melt flows through a central hole of the coil down to the growing crystal below the coil. The FZ technique does not need a crucible. Hence, the melt is not contaminated by other materials. The crystals that are grown according to the FZ technique are called FZ crystals

Fluence

This is the total, time-integrated, flux of particles (electrons, protons, ions, etc.) that reach a unit area of sample. It can be used to represent the total number of ions implanted into a surface and is sometimes called the dose

Fluorescence

Luminescence with a lifetime \lesssim 10 ns

Fluoride Glasses

Multicomponent glasses, typically based on fluorides of zirconium, barium, lead, gallium, lanthanum, aluminum, and sodium. They have a wide transparency range, from ultraviolet to mid-infrared wavelengths. They also have low characteristic phonon energies and can dissolve large concentrations of rare-earth ions. For these reasons, they are extremely popular as hosts for rare-earth-doped amplifiers and lasers operating in the UV-visible and mid-infrared regions

Flux Lines (Vortices)

Regions in which magnetic flux enters a type II superconductor in the mixed state. Screening currents flow around each of the flux lines. Due to the repulsive vortex-vortex interactions a hexagonal flux line lattice is formed

Flux Pinning

An effect caused by defects. The energy for the

formation of the normal cores of the flux lines is reduced in regions with a reduced Cooper-pair density

Flying Height

Spacing between the bottom of the slider and the top of the recording medium in a disk drive

Forced Convection

Process of forced flow of fluid

Fourier-Transform Infrared (FTIR) Spectrometry

A means of performing infrared absorption measurements with great speed and precision, based on an optical interferometer

Four-Point Probe

A popular technique used to measure the resistivity (Ω cm) of a semiconductor sample. Four collinear probes are equally spaced and a current is applied through the outermost probes and the voltage difference across the two inner probes is measured. From the voltage and current values, the resistivity can be calculated assuming that the contact and spreading resistances between the probes and the semiconductor and the resistance of the probes are negligible in comparison to the resistance of the semiconductor

Franck-Condon Principle

Absorption and emission of light takes place in so short a time that the atomic coordinates in ground and excited states are unchanged; i. e. transitions are vertical on a configuration coordinate model

Free Convection

The process of movement of fluid through a temperature gradient

Free Film

Ferromagnetic film in a magnetoresistive or spin-valve read head in which the magnetization can respond easily to an external magnetic field

Friedel's Law

A law that states that the intensity of an hkl reflection in a diffraction pattern is equal to the intensity in the opposite $\bar{h}\bar{k}\bar{l}$ reflection

Front End Of Line (FEOL)

A term generally describing the initial points in the integrated-circuit fabrication process line, such as the transistor fabrication steps. These processes generally require higher thermal budgets

G**Gate Oxide Integrity (GOI)**

The GOI measures the breakdown stability of the oxide layer of a MOS capacitor when a voltage is applied to the capacitor. There are different types of gate oxide integrity tests. Most of them are standardized. This may currently be the best method to detect the density of very small voids

Geminate Recombination

The primary recombination of a correlated

(quasi-bound) hole–electron pair immediately following photoexcitation

Ghosting

The change of X-ray sensitivity of the X-ray image detector as a result of previous exposure to radiation. In the presence of ghosting, a shadow impression of a previously acquired image is visible in subsequent uniform exposures

Giant-Magnetoresistive (GMR) Effect

Change in the resistivity of a stack of ferromagnetic films coupled by thin non-ferromagnetic films when the orientation of the magnetization of the films adjacent to the non-ferromagnetic film is varied. The change in resistivity with low temperatures and high magnetic fields was observed to be as large as 50%; hence the adjective *giant*

Glass Ceramics

Glass that contains crystalline particles or regions. Such materials may be transparent or smoggy

Glass Frit

Binding matrix within the thick film. This binds the active particles together and also bonds the thick film to the substrate

Glass-Transition Temperature

The approximate temperature at which a material changes from a supercooled liquid to an amorphous solid, or vice versa. The transition is marked by an abrupt but continuous change in slope of the specific volume and enthalpy versus temperature curves. Viscosity varies rapidly near the glass-transition temperature, which is also sometimes called the softening temperature

Glow Discharge Spectrometry (GDS)

A method in which a spectrometer is used to measure relevant intensities emitted from a glow discharge generated at a surface. This is a general term that encompasses glow discharge optical-emission spectrometry (GDOES) and glow discharge mass spectrometry (GDMS). GDOES is a method in which an optical-emission spectrometer is used to measure the wavelength and intensity of light emitted from a glow discharge generated at a surface. GDMS is a method in which a mass spectrometer is used to measure the mass-to-charge quotient and abundance of ions from a glow discharge generated at a surface

Gradient Freeze Growth

This technique is similar to the *Bridgman method* except that the melt is not physically removed from the furnace. Instead, the temperature gradient along the melt is controlled electrically so that solidification commences at the seed and progresses until the melt is exhausted. Once again, both horizontal and vertical arrangements are possible and often the reservoir is replaced by liquid encapsulation to impede As loss

from the melt. This is now the favored technique for the growth of most GaAs substrate material

Grading

Grading is the gradual change from one semiconductor to another, exemplified by the gradual change from GaAs to GaAsP that is necessary in some LEDs

Gratzel Cell

Named after its inventor, Michael Gratzel, this is a dye-sensitized cell using a porous TiO₂ substrate to collect the photo-generated charge

GRINSCH Laser

A graded-refractive-index separate-confinement heterojunction laser (*see SCH Laser*). Optical confinement is optimized by grading the composition of the cladding layers

Gunn Diode

(*See negative differential resistance*). This is a device based on low-doped n-type GaAs and relies on the NDR effect. It is used for the generation of low-power microwave currents

H

Hall Effect

The deflection of a charged particle moving in a magnetic field that is perpendicular to its motion. The deflection is due to the Lorentz force on the charged particle and it causes the charges to accumulate in one side of the sample. The voltage measured at right angles to the current flow is called the Hall voltage. The Hall effect can be used to characterize the mobility (cm²/Vs), resistivity (Ω cm), type of carrier and carrier density (cm^{−3}) of a semiconductor sample. The *Hall mobility* is the product of conductivity and the Hall constant (the transverse-electric-field Hall field divided by the product of the current density and the magnetic induction) for a conductor or semiconductor; a measure of the mobility of the electrons or holes in a semiconductor. The *Hall coefficient* and *factor* relate μ^H linearly to σ and μ , respectively

Hard Axis

Direction in a ferromagnetic sample at right angles to the easy axis

Hard Magnetic Bias Film (also Longitudinal Bias Film)

Permanent magnetic film abutted to the free film in a magnetoresistive or spin-valve head to eliminate magnetic domains

Head Field Slope Parameter (Q)

The maximum slope of the magnetic field of a write head in the direction of the magnetization of the recording layer normalized to the coercive field (H_c) divided by the magnetic spacing (d), $Q = \frac{dH_x/dx}{H_c/d}$

Heat Capacity

The amount of heat required to change the

temperature of a substance temperature by one degree, with units of energy per degree

Heteroepitaxy

The growth of a layer of markedly different composition from the substrate, i.e. the epitaxial layer and the substrate are made from different materials, e.g. the diamond growth on an iridium single-crystal substrate. Another example is the growth of $\text{Ga}_x\text{In}_{1-x}\text{P}_y\text{As}_{1-y}$ layers lattice-matched to InP. The heteroepitaxial growth techniques are chemical-vapor deposition, liquid-phase epitaxy, and molecular-beam epitaxy

Heterojunction Bipolar Transistor (HBT)

A modification to the standard bipolar transistor where a heterojunction is used to control the carrier flow at the base

Heterojunctions and Heterostructures

A heterojunction is the junction between different materials (e.g. GaAs and AlGaAs with different bandgaps). Such a junction exhibits several properties that may be very useful to device manufacturers. These include changes in the energies of the valence or conduction bands, or both, and changes in the optical properties. A heterostructure is a semiconductor structure where the properties of heterojunctions are exploited

Heterojunction Laser

A semiconductor laser where both electrical and optical confinement exploit the properties of heterojunctions is a heterojunction laser. If the active region is sandwiched between two heterojunctions, the laser is termed a double heterojunction

Hexagonal As

The natural form of elemental arsenic

HgMnTe

An alternative Hg-based ternary system to *CMT*

High-Electron-Mobility Transistor (HEMT)

This is a modification of the *metal semiconductor field-effect transistor (MESFET)* where the separation of the electrons in the channel from the ionized donors is achieved by using a heterojunction. This results in higher electron mobility, and thus greater speed and lower noise

High Index Contrast

Waveguides or devices fabricated using two or more materials that have very different refractive index. High index contrast is the basis for the confinement of light to very small cross-sectional-area waveguides or very-small-volume optical cavities, either using total internal reflection or photonic bandgap effects. High index contrast is thus the basis for increased density of optical integrated circuits

High-Temperature Solution Growth

Slow cooling, or top-seeded (similar to Czochralski) growth of materials in a solution designed to reduce

the freezing point of the desired phase below a critical temperature

Homeotropic Alignment

Alignment of the director perpendicular to the surface of a substrate

HOMO – Highest Occupied Molecular Orbital

The highest energy molecular orbital of an atom or molecule that contains an electron. If the atom or molecule were to lose an electron, it would most likely lose it from this orbital

Homoeptitaxy

Epitaxial growth of a layer of the same composition as the substrate

Homojunction

Junction between materials of the same chemical type but of different electrical properties. For example, a p–n junction in GaAs is a homojunction

Hopping Conduction

Electronic transport that localized electrons hop from site to site with the assistance of phonons

Hot-Carrier Phenomena

Group of effects associated with the carrier transport in high electric fields. For Si, it includes the nonlinear relation between drift velocity and electric field with saturation (n-Si) and near to saturation (p-Si), anisotropy of drift velocity regarding the electric orientation relative to the crystallographic axes (the Sasaki–Shibuya effect) and the diffusion's anisotropy as regards the density gradients along and perpendicular to the strong electric field

Hot-Wire Chemical Vapor Deposition (CVD)

The same technique as catalytic CVD, which is used for thin-film growth through decomposition of source gas materials utilizing catalytic reaction on the heated filament

Huygens's Principle

Concept used to explain the propagation of a wave (and diffraction processes), in that every point on a primary wavefront acts as a source of spherical wavelets, the envelope function of which acts to reconstruct the primary wavefront a short time later

Hybrid Circuits

Circuits consisting of electronic elements made from differing enabling technologies such as thick-film, thin-film, monolithic silicon, etc.

Hybridization

In molecules, the orbitals occupied by the electrons are seldom pure s or pure p orbitals. Instead they are mixed or hybrids, formed by combining the s and p orbitals. Examples are sp (linear), sp² (trigonal and planar) and sp³ (tetragonal)

Hydrothermal Growth

Growth that takes place in aqueous-based solutions at high temperatures and high pressures

Hysteresis

The state of the magnetization in response to an external magnetic field depends on the initial state of the magnetization

***I/V* Technique (Current–Voltage Technique)**

The *I/V* technique is a method to determine barrier heights and ideality factors of Schottky contacts from their current–voltage characteristics

IDCA

Abbreviation for for integrated detector cooler assembly, a commonly used infrared detector scheme in which the detector is mounted directly on the cold finger of a cryocooler (often based on Stirling cycle engines). The detector and cold finger are then enclosed in a vacuum vessel with a transparent window and optical baffles

Ideality Factor

The ideality factor of Schottky contacts characterizes the variation of their barrier heights as a function of applied voltage

Image Lag

Lag is the carryover of image charge generated by previous X-ray exposures into subsequent image frames. The residual signal fractions following a pulsed X-ray irradiation are referred to as image lag

Impact Ionization

Process of generation of electron–hole pairs by carriers moving in an electric field higher than the breakdown threshold, which for Si is of the order of 3×10^5 V/cm

Improper (or Extrinsic) Ferroelectric

A ferroelectric material in which the spontaneous polarization is not the primary order parameter. Frequently, the primary order parameter is the spontaneous strain associated with a ferroelastic phase transition

Impurity

A foreign atom unintentionally present in the semiconductor, incorporated either during growth or processing

***In Situ* Monitoring**

Tools to help in understanding layer growth kinetics and to provide monitors suitable for feedback control in epitaxial growth systems

Inelastic Scattering

The result of a collision between a photon or electron and the nuclei or electrons of a material, such that there is a net change in the internal energies of the system and in the sum of the kinetic energies before and after the collision

Infrared-Laser-Absorption Spectroscopy (IRLAS)

Technique to determine density of gas-phase

molecules and chemical species using infrared absorption spectra

Infrared-Reflection-Absorption Spectroscopy (IRRAS)

Technique to determine the surface-bonding configuration on the film-growing surface using light absorption during reflection of infrared beam

Integrated Circuit (IC)

Combination of active and passive circuit elements to enable computational logic or analog operations

Integrated Optics/Photonics

The manufacture of photonic elements and circuits on a planar substrate, typically using thin-film deposition, lithography, and etching steps. Typically, the substrate is a glass or semiconductor wafer and the photonic elements are guided-wave devices

Interconnect

The system of metal conducting lines and contacts among IC components. The categories include local (between neighboring devices), intermediate (between neighboring circuit elements), and global (across the IC chip)

Interdiffused Multilayer Process (IMP)

The process of obtaining a uniform alloy composition of $\text{Cd}_x\text{Hg}_{1-x}\text{Te}$ by the growth of alternate layers of the binary compounds that are thin enough to completely interdiffuse within the time of growth

Interface Trap Density

The density (cm^{-3}) of positive or negative charges located at the silicon/silicon dioxide interface, due to defects induced by oxidation, structural defects, impurities or other defects caused by bond-breaking mechanisms such as radiation or hot carriers. These states are typically in electrical communication with the charges in the channel of a MOSFET and results in stretch-out of the capacitance–voltage characteristics. They also affect the turn-on and turn-off characteristics of a MOS transistor

Interface-Induced Gap States

Because of the quantum-mechanical tunnel effect, the wave-functions of electrons tail across semiconductor interfaces in energy regions where occupied states overlap a bandgap. These evanescent waves are the continuum of the *intrinsic* interface-induced gap states

Intergrain j_c

Macroscopic transport critical current density, which can be much smaller than the intragrain j_c because of the weak-link behavior of large-angle grain boundaries in the cuprate superconductors

Intermetallic Compounds

Substances that form between pad metallizations and the active components of molten solder (typically Sn). For Cu metallization, the Sn reacts to form Cu_3Sn and Cu_6Sn_5 intermetallics. For Ni, the Sn reacts to form Ni_3Sn_4 . These intermetallics typically form at the interface of the solder and the metallization and

are usually more brittle than the solder or the metallization

Intermetallic Reactions And Phases

Two or more metals can react chemically to produce compounds. These are revealed in phase diagrams as labeled, vertical lines. The compound is often referred to as an intermetallic phase

Interstitial

A site lying between regular lattice sites that can be occupied by dopant, impurity or host atoms. The latter case is known as a self-interstitial. They generally behave as a donor

Inter-subband (ISB) Transition

Transition between confined states within the conduction or valence bands

Intragrain j_c

is the value of j_c within a single grain, limited only by the pinning properties

Intrinsic Point Defect

Is the general term for either a vacancy or a Si interstitial in the Si matrix

Inversion

Condition in which, for a MIS structure, the applied voltage to the gate electrode V_G results in an increase of minority carriers near the surface of the underlying semiconductor. This region is referred to as an inversion layer. When present in a MISFET, this condition results in a conducting channel between the source and drain regions. This condition occurs for applied voltages beyond the threshold voltage, i. e. $V_{th} < V_G$

Inversion Symmetry

A system in which the laws of physics are unchanged by the operation of inversion

Ion Implantation

This is a method of introducing impurities into the surface of a solid. The impurity atoms to be introduced are ionized and accelerated by a high voltage, up to 10^6 V in some instances. They penetrate the surface to a depth dependent on their energy. Unfortunately, this disrupts the crystal lattice by introducing irradiation damage and this must be repaired by annealing at elevated temperatures before the electrical activity of the implanted atoms can be obtained

Ionization

Process of forming an electrically charged atom (ion)

Ionization Energy

The energy distance from the valence-band maximum to the vacuum level at the semiconductor surfaces

IPEYS technique (Internal Photoemission Yield**Spectroscopy)**

IPEYS is a method to determine barrier heights of Schottky contacts and band offsets of semiconductor heterostructures by photoinjection of hot electrons over the energy barriers at metal/semiconductor and

semiconductor/semiconductor interfaces, respectively, as a function of the photon energy of the exciting light

Irreversibility Line

Situated well below the upper critical field, this line separates a region without pinning and zero j_c , above the irreversibility field, from a region with pinned vortices ($j_c > 0$)

Irvin Curve

The experimental resistivity ρ of Si at room temperature versus N , the free-carrier concentration

K

Kikuchi Lines

Diffuse background of lines in a diffraction pattern formed by the elastic scattering of incoherently scattered electrons

Knudsen Cell

High-vacuum oven from which molecular beams can be produced in molecular-beam epitaxy. These ovens are usually fitted with temperature sensors. Shutters mounted in front allow the beams to be turned on and off, as required

Kramers–Kronig Relations (KKR)

Dual integral relations between the real and imaginary parts of one-sided Fourier transform of causal functions of time, which includes all physical admittances. The KKR allow us to define the optical constants based on KKR relations for amplitude and phase of complex reflection coefficient from opaque sample of material under measurement

Kypopoulos Technique

This is similar to the Czochralski method but the extent of pulling is limited, producing crystals of greater diameter but shorter length

L

Langmuir–Blodgett Film Deposition

Method to build up multilayer structures of organic materials by the transfer of a monolayer floating on a water surface to a solid substrate as the latter is raised and lowered through the monolayer/water interface. Deposition modes include Y-type (monolayer transfer from the water surface to the substrate on both the upward and downward motion of the latter through the monolayer/air interface), X-type (film transfer only on downward motion of the substrate) and Z-type (film transfer only on the upstroke)

Laporte's Rule

Transitions between states of the same parity are forbidden

Laser Crystallization

A useful method to fabricate polycrystalline semiconductor showing high electron mobility by

irradiating laser beam on amorphous semiconductor thin films

Laser-Induced Fluorescence (LIF)

Technique to determine the density of gas-phase atoms and molecules whose optically excited states are emissive states

Lattice-Matching

Growth of quantum wells on a substrate with the same, or very similar, lattice constant

Law of Mass Action

An equation linking the concentrations of the various reacting species in a chemical-type equation, derived from defect chemistry analysis

Lifetime

Minority-carrier lifetime is one of the electrical parameters that determines the performance of IR devices; it can be affected by impurities and/or dopants

Light-Induced Defect Creation

The defect creation associated with illumination of samples. This is normally observed in amorphous materials having a flexible network

Lineage

A reduction in total dislocation strain energy can be obtained either by polygonization or by dislocations arranging themselves in linear arrays. The latter results in the creation of a small-angle grain boundary or lineage. The reader will find examples of this in most books on materials science

Liquid Crystal

State of matter with properties characteristic of both a liquid and a crystal; that is, it flows like a liquid and certain properties are anisotropic like those of a crystal. At the molecular level the phase has long-range orientational order and some element of translational disorder at long range

Liquid-Encapsulated Czochralski Technique

An inert layer, usually B_2O_3 , is used, which floats on the top of the melt to prevent loss of volatile components; this is used for As- and P-containing compounds

Liquid-Phase Epitaxy (LPE)

LPE is epitaxial growth of a layer by dissolving the required material in a liquid. On cooling, the material becomes supersaturated and forms a solid film. If this film is deposited on a substrate the growth can be epitaxial

Localized Vibrational Mode (LVM) Absorption

Form of mid- to far-infrared absorption resulting from simple vibrations of light atoms in a heavier lattice. Such vibrations do not couple well to lattice vibrations and result in sharp absorption lines whose frequencies are directly related to mass and whose strengths are proportional to concentration. LVM absorption is particularly suited for measuring carbon concentrations in SI GaAs

Longitudinal Magnetic Recording

Recording system consisting of write and read head and a recording media where the magnetization is parallel to the surface of the recording medium

Long-Range Disorder

Defined by the absence of the long-range order, i. e. the lack of periodic arrangements of atoms

Low-Dimensional Structure

Heterostructure with dimensions comparable to the wavelength of an electron or hole, typically less than 100 Å, so that quantum effects are important

Low-Frequency Noise

Electrical measurement of the current or voltage noise spectral densities of a semiconductor component, typically at frequencies from ≈ 1 Hz to ≈ 100 kHz. The units are in A^2/Hz for current noise spectral density and V^2/Hz for voltage noise spectral density. It is a sensitive electrical technique that can be used to probe microscopic defects in semiconductor components and as a gauge of their reliability

Low-Temperature Co-fired Ceramic (LTCC)

A composite material structure made of alumina bonded at a temperature below the sintering temperature of alumina using a glass binder. In a substrate form, LTCC can be co-fired (melting the glass and bonding the alumina while capturing the metal interconnects and lines) at lower temperatures so it is possible to use higher conductivity materials like Cu or Ag conductors in the ceramic

Low-Temperature Solution Growth

Normally used for water-soluble materials, with growth being progressed by either slow cooling or solvent evaporation

LPE

Liquid-phase epitaxy is growth of a (normally) thin epitaxial layer from the liquid phase onto a suitably lattice-matched substrate by dipping, tipping or sliding boat means

L-pit

see A-swirl

Luminescence

In general terms, is the emission of light by a luminescent material (also called phosphor) due to conversion of a certain type of energy into electromagnetic radiation over and above thermal radiation. The luminescence is the light emitted by nonthermal sources in contrast with the emission of radiation from a heated object, which is called incandescence. In accordance with the source of energy the luminescence may be the photoluminescence (excited by external illumination), electroluminescence (induced by the passage of electrical current), cathodoluminescence (excited by irradiation with electrons), triboluminescence (excited by mechanical treatment, e.g. grinding), chemiluminescence (emitted during chemical

reaction), bioluminescence (appearing as a result of biological processes), thermoluminescence (caused by the rise of temperature) and so on

LUMO – Lowest Unoccupied Molecular Orbital

Refers to the lowest-energy molecular orbital of an atom or molecule that does not contain an electron. If the atom or molecule were to accept an electron, it would be most likely to do it with this orbital

LW

Abbreviation for long wave, this term refers to the transparent atmospheric window between the wavelengths 7.5 μm and 14 μm (sometimes called the thermal band). The edges of this window are influenced by the water-vapor content and atmospheric conditions

M

Magnetic Annealing

Thermal process involving a ferromagnetic sample in a magnetic field in which the sample has induced a direction of easy magnetization (easy axis)

Magnetic Random-Access Memory (MRAM)

Digital memory device composed of ferromagnetic thin films coupled to current-carrying conductors used to establish the direction of the magnetization in the ferromagnetic films. The resistance of the coupled films is different when the direction of magnetization in the two ferromagnetic films is changed

Magnetic Spacing

Spacing between the bottom of the slider and the center of the ferromagnetic storage layer in a recording medium characterized by the magnetic spacing parameter d

Magnetic Transition

In digital magnetic recording, the region between opposite states of the magnetization in the recording medium. The length of the transition (l) is $l = \pi a$, where a is the transition parameter

Magnetic Tunneling Junction (MTJ)

MRAM in which the magnetic state of the ferromagnetic sample is sensed by the change in resistance of electron current tunneling through a thin insulating layer when the magnetization in the two electrodes coupled to the ferromagnetic sample is changed from parallel to antiparallel orientation

Magnetoresistance

Change in resistance of a ferromagnetic material due to changes in the orientation of the magnetization with respect to an induced easy axis. Sometimes referred to as the anisotropic magnetoresistance (AMR). Characterized by the change in resistivity with magnetic field normalized to the nominal resistivity $\Delta\rho/\rho$

Magnetoresistivity (MR)

Change of resistivity ρ in applied magnetic field. For Si, MR is a diverse tensor reflecting the symmetry of the CB and VB

Majority Carriers

Electrons in an n-type and holes in a p-type semiconductor. Majority-carrier mobility is the mobility of electrons (holes) in n-type (p-type) material

Media Flux

Product of the remanent magnetization and the thickness of a magnetic recording film

Media Noise

Noise voltage at the terminals of a read head caused by fluctuations in the magnetization of the recording media

Mercury-Sensitized Photo-CVD

Technique for preparing thin films by decomposing source gas materials by collision with photo-excited mercury atoms

Mesogen

This is a molecular compound or mixture of compounds capable of forming a liquid-crystal phase over a range of temperatures between the crystal and isotropic liquid phases

Metal Semiconductor Field-Effect Transistor (MESFET)

Probably the simplest three-terminal device that can be fabricated on GaAs. The “metal semiconductor” refers to the gate structure, which is a simple Schottky barrier. The application of a reverse bias to this gate produces a depleted region that occludes part of the cross-sectional area of the channel, and thus modifies its conductivity

Metallic Nanocomposites

Composite materials made out of metallic quantum dots embedded in organic or glass hosts

Metastability

A term that refers to the nonequilibrium nature of glasses or amorphous solids. Amorphous solids have excess internal energy relative to the corresponding crystalline state or states of the same material. The method of manufacture, such as melt quenching, inhibits a transition to the lowest-energy crystalline state

Microphotonics

Refers to the chip-scale manufacture of optical and photonic waveguide circuitry, using processing techniques borrowed from the microelectronics industry. Related to this is the need for high-density integrated optics, as facilitated by high-index-contrast waveguides and photonic crystals. By usual definition, microphotonics refers specifically to the monolithic manufacture of optical and photonic elements on silicon (CMOS) chips

Miller's Rule

An empirical rule proposed by Miller in 1964, which suggests that $\chi^{(2)}/\{\chi^{(1)}\}^3$ is nearly constant for all non-centrosymmetric crystals

Miniband

Interval of allowed energies for carriers in a superlattice, resulting from the delocalization and broadening of the quantum-well energy levels

Minority Carriers

Electrons in a p-type and holes in an n-type semiconductor. Many electron devices work on the base of minority-carriers transport. Minority-carrier mobility is the mobility of electrons (holes) in p-type (n-type) material

MIS

Abbreviation for structure metal/insulator/semiconductor (see MOS)

Misfit Dislocations

These are dislocations introduced near the boundary of an epitaxial layer and the substrate, when a mismatch between the lattice constants exists. The density of these dislocations is proportional to the mismatch. Although they run parallel to the boundary, they can interact and penetrate much of the epitaxial layer; see threading dislocations

Mixed State

In type II superconductors this state exists between the lower and upper critical fields. In the mixed state superconducting and normal regions coexist. Magnetic flux enters the superconductor in the normal cores of the flux lines

Mobility Edge

The boundary between localized and delocalized states in a band

Mobility Gap

Energy separation between two mobility edges of the conduction and valence bands

Mobility

Parameter defined as the ratio of the carrier velocity (cm/s) to the electric field through which it is moving (V/cm). It is expressed in units of cm^2/Vs . At the microscopic level, it is related to the dominant scattering time and the effective mass of the carrier. The notion includes drift mobility μ , which corresponds to the motion parallel to the field and Hall mobility μ^H , which corresponds to motion perpendicular to the electric field, when a magnetic field is applied

MOCVD

Technique for depositing thin films of compound semiconductors from a chemically reactive vapor phase where at least one of the components is a metal-organic

Modulation Transfer Function (MTF)

The MTF measures the efficiency of an imaging system such as a detector to resolve (transfer) different

spatial frequencies of information in an image. In other words, the MTF is the relative signal response of the system as a function spatial frequency

Molecular-Beam Epitaxy (MBE)

Low-temperature growth technique for epitaxial films from atomic or molecular beams from thermal evaporation sources. It is carried out in ultra-high vacuum. CBE is a form of molecular-beam epitaxy in which group III and group V beams are generated from external gas sources. MOMBE is a form of MBE where some or all beams are generated from external gas sources, in III–V MBE only the group III beams, from metal-organic sources. GSMBE is a form of MBE where some or all beams are generated from external gas sources, in III–V MBE only the group V beams, from hydride sources

Molecular Electronics

Exploitation of organic materials for electronics and optoelectronics applications. Examples are displays based on liquid crystals and organic electroluminescent polymers. In the case of organic polymers, the area is sometimes referred to as plastic electronics

Molecular Reorientation

Nonlinear process in which the orientation of molecules in liquid changes upon illumination with intense light

Molecularly Doped Polymers (MDP)

Formulations of charge-transport materials dissolved in a polymer matrix. CTLs of OPCs are typically MDPs

Monolayer (ML)

A single layer of atoms (in III–V MBE a layer of the compound or alloy, e.g. a layer of Ga + As)

Moore's Law

prediction based upon the empirical observation by G. Moore that the minimum cost of manufacturing integrated circuits per component actually decreases with the increase in the number of IC components, and thus with greater circuit functionality and computing power. A corollary of this observation is that the density of integrated circuit transistors will double roughly every 1.5–2 years (see scaling)

MOS

Abbreviation for a metal/oxide/semiconductor structure, which is one possible realization of MIS. The insulator has traditionally been SiO_2 (the oxide) due to superior materials and electrical properties, resulting in the abbreviation MOS

Moseley's Law

States that the square root of the frequency of characteristic X-rays, for certain elements, is linearly related to the atomic number

MOVPE

Metalorganic vapor-phase epitaxy is a low-temperature growth technique using metalalkyls

(and elemental Hg in the case of Hg-based ternary compounds) as the sources

MPCVD Technique

(Microwave plasma chemical deposition technique) A technique for film deposition. This is now the most widely used technique for diamond growth. Energy is transferred by the microwaves to gas-phase electrons, which transfer their energy to the gas through collisions. The gas molecules dissociate and the active species are formed and the deposition of diamond onto the substrate immersed in the plasma occurs

Multi-Crystalline Silicon (mc-Si)

Wafers of silicon, cheaper to produce than the single-crystal silicon wafers but have multiple single-crystal grains in each wafer

Multiple Quantum Well (MQW)

Structure composed of a stack of QWs separated by sufficiently thick barriers so that the electron wave functions and energy levels are localized to each QW

MW

Abbreviation for medium wave, the term for the transparent atmospheric window between the wavelengths 3.3 μm and 5 μm . There is a CO_2 absorption band around 4.25 μm which divides the band into two with the better atmospheric transmission in the 3.3 to 4.2 μm band

N

Narrow Bandgap

Refers to a semiconductor with a forbidden energy gap of less than about 0.7 eV, making it suitable for detection in the infrared wavebands

Native Defect

A vacancy, a self-interstitial, an anti-site or any complex of these

Negative Differential Resistance (NDR)

(see, transferred electron effect). In GaAs, electrons that undergo the transferred electron effect, are excited from the primary conduction band minimum where their effective mass is low to subsidiary minima where their effective mass is considerably greater. As a result, although they have greater kinetic energy, their drift velocity is lower. This, in turn, results in a reduction of current in the external circuit. The current-voltage characteristics show a reduction in current after a critical voltage is applied (although the ratio of current to voltage will always be positive). This is NDR. It can be shown that current flow in the NDR region is unstable and that charge tends to be transported in groups, resulting in oscillations in the current flow. This is the Gunn effect and is used in some microwave sources

Nematic Phase

is the simplest of the liquid-crystal phases; it has

long-range orientational order but is devoid of long-range translational order

NETD

Noise-equivalent temperature difference is a measure of sensitivity for a multiplexed infrared detector and is the change in scene temperature that produces a signal equivalent to the rms noise level of the detector

Nonlinear Directional Coupler

A device where a part of one of two waveguides is made out of a nonlinear material. Changing the intensity of the incident light changes the effective path length experienced by the waveguided light, thus controlling coupling between the two waveguides

Nonlinear Fabry-Perot Interferometer

A device that consists of two mirrors separated by a nonlinear material. As the refractive index of the nonlinear material changes with an increased level of illumination, the effective path length of the resonator is altered, changing the transmission properties of the device

Nonlinear Figure Of Merit

A figure of merit that describes the applicability of a refractive nonlinear optical material in terms of nonlinear index change and effective absorption

Nonlinear Kramers-Kronig Transformations

A set of two relations that permits calculation of the real (imaginary) part of nonlinear response at a given optical frequency given the knowledge of the imaginary (real) nonlinear response at all other optical frequencies

Nonlinear Mach-Zehnder Modulator

A Mach-Zehnder modulator in which a part of the waveguide is made out of a nonlinear material. Changing the intensity of the incident light changes the effective path length experienced by the light in the nonlinear waveguide, controlling transmission

Nonlinear Material Figures Of Merit

A set of metrics that allows us to quantify the applicability of a nonlinear optical material to optical switching

Nonlinear Optical Medium

A material whose properties change upon illumination with intense light

Nonlinear Optical Switching

Switching of optical signals using an illumination-dependent phase shift of nonlinear materials

Nonlinear Periodic Structure

A Bragg periodic structure in which at least one set of layers is nonlinear

Nonlinear Phase Shift

A difference between the phase shift experienced by intense light and a phase shift experienced by light which intensity approaches zero

Nonlinear Polarization

Polarization that does not experience purely linear dependence on the electric field

Non-stoichiometry

Defined as the difference between the total anion and cation concentrations, hence anion- or cation-rich

n-Type Conductivity

A semiconductor material, with electrons as the majority charge carriers, that is formed by doping with donor atoms

Nucleation Temperature

Temperature where stable defect clusters/aggregates start to form as nuclei

Numerical Aperture

Figure of merit used to describe the power of a lens, depending on the angle of collection of the lens and the refractive index of the medium in which the lens is situated

O

Onsager Model

A model that describes the probability of geminate recombination as a function of applied field with the efficiency of geminate pair photogeneration and the initial pair-separation distance as parameters

Optical Absorption Coefficient

4π times extinction index, divided by the radiation wavelength

Optical Bistability

A phenomenon in which the instantaneous transmittance of the device depends both on the level of incident illumination and on the prior transmittance of the device. Such an element enables all-optical switches

Optical Constants

The real and imaginary parts of the square root of the *dielectric constant/susceptibility*, called the refraction and extinction index, respectively; they define the optical properties of bulk material and mesoscale structures

Optical Emission Spectroscopy (OES)

A technique to determine the plasma parameter and reactions in the plasma by measuring the emission intensity of line spectra from the plasma

Optical Gap

(See *Bandgap*)

Optical Limiter

A device in which the transmittance decreases with increased level of illumination

Optical Properties of Sample

These include the apparent reflectance, transmittance and absorbance

Optical Texture

Pattern observed for thin slabs of birefringent material between crossed polarizers under a microscope. It is

used as a fingerprint to help identify the many different liquid-crystal phases

Optically Detected Magnetic Resonance

Magnetic resonance observed by optical means, particularly by detection of electron spin resonance by monitoring luminescence intensity and polarization, etc.

Order Parameter

The parameter that measures the extent of long-range order characteristic of a phase. The orientational order parameter is the most important for liquid crystals; by definition it vanishes in the isotropic phase

Organic Photoconductors (OPC)

Single material or a formulated blend of materials that have photoconductive characteristics

Organic Photoreceptors

Thin-film multilayer devices made from organic photoconductive materials. These devices are often called organic photoconductors

Oscillator Strength

Measure of the probability of a transition between levels; an oscillator strength of 0.01–1 is highly probable (*allowed*) and has a short lifetime (ns), one less than 0.001 is improbable (partially *forbidden*) and has a long lifetime (μs –ms)

Oxidation-Induced Stacking Fault

A stacking fault that shows up after wafer oxidation. During oxidation, Si interstitials are injected from the wafer surface into the bulk. They aggregate around oxygen precipitates of a critical size and thereby squeeze an additional lattice plane (stacking fault) between two regular lattice planes

Oxygen Precipitates

Aggregates of oxygen atoms that form in Czochralski-grown crystals due to their relatively large oxygen content. The silica crucible that holds the Si melt is slowly dissolved during the growth process that introduces oxygen into the melt and, hence, into the growing crystal

P

Paraelectric

Nonpolar phase that transforms into the ferroelectric phase at the Curie temperature

Partial Response Maximum-Likelihood (PRML) Recording Channel

Particular form of equalization used in digital recording channels. The detector is maximum likelihood

Passivation

Passivation refers to the removal of electrical activity of a defect, often by trapping a mobile atom of the opposite electrical type (a donor may trap a mobile acceptor, for example). The defect now becomes a complex, consisting of the original defect and the

new component in close proximity, but without electrical properties. Unlike compensation, ionized impurity scattering is reduced by passivation and carrier mobility is increased

Passive Matrix Addressing

Also known as simple multiplexing, passive matrix addressing is a technique for writing images onto liquid-crystal displays. The display elements are arranged as a matrix of rows and columns, and a series of voltage pulses are applied to each row in sequence. Individual pixels are activated by applying a voltage to the relevant column, such that the sum of the row and column voltages exceeds the desired switching or threshold voltage. Each pixel responds to the root mean square voltage applied during the line-address time, and unlike the active-matrix addressed displays, there is no charge-storage facility. Thus, the number of rows that can be addressed is limited

PECVD Technique

An abbreviation for plasma-enhanced chemical vapor deposition. Like CVD, this is a technique for thin-film deposition. In contrast to the CVD technique, in the PECVD technique the deposition of a film is a nonequilibrium process. The gas-phase reactions, which are activated by temperature in the CVD technique, originate in the PECVD technique from an interaction of electrons with the gas molecules injected in the reaction chamber. In the plasma the dissociation of the gas precursors is obtained by their collisions with energetic electrons. The products of the reactions interact with the substrate surface and leads to the deposition of a thin film. As the dissociation of the gases is produced by electron impacts, the reactor and substrate can be kept at room temperature

Penetration Depth (λ_L)

The characteristic length scale for the penetration of a magnetic field into the surface layer of a superconductor

Perfect Diamagnetism (Meissner Effect)

Of the superconducting state is reflected by the fact that a magnetic field is expelled from the interior of a field-cooled superconductor as soon as the superconducting state is reached

Permalloy

Alloy of nickel and iron with approximately 80% Ni and 20% Fe. Composition of alloy with zero magnetostriction

Permittivity (ϵ)

A measure of the polarizability of a dielectric material, which is frequency dependent. The relative permittivity of a material is often given by ϵ or ϵ_r , such as with the parallel-plate capacitor expression for capacitance: $C = \epsilon\epsilon_0 A/t$. (See also *dielectric constant*.)

Perpendicular Magnetic Recording

Recording system consisting of write and read head

and a recording media where the magnetization is perpendicular to the surface of the recording medium

PES Technique (Photoemission Spectroscopy)

PES is a method to determine the barrier heights of Schottky contacts and band offsets of semiconductor heterostructures from energy-distribution curves of electrons photoemitted from Schottky contacts and semiconductor heterostructures excited by ultraviolet light (UPS), soft X-rays (SXPS) and X-rays (XPS)

Phonons

Quantized lattice vibrations in a solid

Phosphorescence

Luminescence with a lifetime $\gtrsim 10$ ns, typically involving a metastable state in the pumping cycle

Photo-Thermal Ionization Spectroscopy

A very sensitive technique for the measurement and identification of shallow impurities in semiconductors. The measurement is a two-stage process; the absorption of light excites the electron on un-ionized donors into a higher level and thermal energy now ionizes this electron into the conduction band, where it can be measured as a photo-current. Because the energy of the optical ionization is dependent on the donor type, the photocurrent spectrum as a function of photon energy, displays peaks that are characteristic of the donors present

Photo-catalysis

An enhancement of the reaction rate on the surface by shining UV radiation onto the growing film

Photochromic

Temporal coloring induced by (UV) light illumination. For instance, photo-structural changes of Ag particles, which are dispersed in oxide glasses

Photoconductivity

The part of the conductivity that is caused by the absorption of light. Negative values of the photoconductivity are possible when optical excitation activates efficient carrier traps. A photoconductive device uses the change in resistance of a slab of semiconductor to measure the extra electron-hole pairs created by the absorption of photons

Photocurrent

The current that is generated as a result of absorption of light

Photodarkening

Quasi-stable darkening induced by light illumination. In chalcogenide glasses, it occurs with a red-shift of optical absorption edge, which is induced through athermal photo-structural processes. The process, however, is speculative

Photoinduced Degradation

A deterioration of semiconductor properties by prolonged light exposure

Photoinduced Discharge Characteristic (PIDC)

Plot of exposed potential versus exposure using either

a continuous exposure or flash exposures of varying intensity

Photoinduced Effects

Changes in the properties of a glass induced by light, involving transitions between metastable states of the glass or changes in defect sites within the glass. Typically, a laser beam is used to locally modify the refractive index, density, absorption coefficient, etc. of the glass (see photodarkening, photo-induced degradation). These processes are widely used to pattern photonic structures such as Bragg gratings, waveguides, and refractive lenses into glasses

Photoisomerization

Light-induced change in the molecular structure of a molecule

Photoluminescence

Luminescence excited by the external illumination of the material. It should be distinguished from reflection and light scattering, which are also caused by external illumination and are not connected with thermal radiation of the material too. The criterion to distinguish these phenomena is the characteristic decay time after the cessation of the incident light. While reflection and scattering would decay within $\approx 10^{-14}$ s (characteristic time of electromagnetic oscillations of incident light wave) the photoluminescence would persist at least more than $\approx 10^{-12}$ s (characteristic time of atomic vibrations of luminescent material)

Photon

A quantum of electromagnetic radiation

Photonic Glass

High-purity glasses in which impurities are controlled or suppressed at ppm levels. An example is the optical fiber glass developed at the end of the 20th century, which is very recent when compared to a long history of artificial glasses of 5000 years

Photorefractive Beam Fanning

Spreading of an intense light beam due to the photorefractive properties of a material

Photosensitivity

of an organic photoconductor is a measure of the rate of photodischarge when exposed to light. Typical characterizations are the initial slope of the photodischarge (volts/J) and the energy required for photodischarge to half the initial surface potential

Photovoltaic Device

Utilizes a p–n junction in a semiconductor to separate electron–hole pairs (created by the absorption of photons) to generate a voltage

Photovoltaic Module

A complete encapsulated device suitable for mounting on a roof or building façade. Modules will often comprise of a number of cells and typical size is of the order of 1 m^2

Photovoltaic Solar Cell

A semiconductor device for conversion of solar energy into electricity

Piezoelectric Polarization

Generation of electric polarization in certain dielectric crystals as a result of the application of mechanical stress

Piezoelectricity

Property of some crystalline materials, which produce an electric charge when subjected to an externally applied force (direct effect). They also deform when subjected to an external electric field (reverse effect)

Piezoresistivity

Property of certain materials, including thick-film resistors, whereby an externally applied force gives rise to a change in resistance

Pinned Film

Coupling of a ferromagnetic to an antiferromagnetic film resulting in the magnetization of the ferromagnetic film being constrained to a fixed direction. The strength of the coupling is characterized by an exchange field parameter (H_{ua}) measured in Oe or A/m

Pixie Dust

Thin layer of Ru as used in synthetic antiferromagnetic media (SAF)

Planar Lightwave Circuit (PLC)

The industrially established processes for manufacturing integrated optics devices in silica-based glasses deposited on silicon wafers. Typically, the glass layers are deposited by chemical vapor deposition or flame hydrolysis. These technologies were developed mainly for applications in fiber optics, and are widely used to manufacture wavelength multiplexers

Plasmon

Quantized collective motions of electron gas in a metal. In a bulk metal, the plasmon propagates as a longitudinal wave, which may be probed by an electron beam. In a metal nanoparticle, a transversal surface plasmon can be excited by light waves

Plastic Deformation

Deformation of a body caused by an applied stress, which remains after the stress is removed

Plastic Electronics

Use of polymers in electronic and optoelectronic devices (See also *molecular electronics*)

Point Defect

Smallest structural element, or imperfection, to cause departure from a perfect lattice structure, e.g. a dopant or impurity atom

Poisson's Equation

A differential equation relating the spatial gradient of the local electric field to the local space-charge density

Poisson's Ratio ν

The ratio of transverse contraction strain to longitudinal extension strain in the direction of stretching force. Tensile deformation is considered positive and compressive deformation is considered negative. The definition of Poisson's ratio contains a minus sign so that normal materials have a positive ratio

Polarity

Property of a physical system that has two points with different characteristics, such as one that has opposite charges or electric potentials

Polarization Ratio

The density of states at the Fermi energy in an energy band for electrons in a metal with spins parallel (antiparallel) to the local magnetization is $D(E_F^\uparrow)$ and $D(E_F^\downarrow)$, respectively. The polarization ratio is

$$P = \frac{D(E_F^\uparrow) - D(E_F^\downarrow)}{D(E_F^\uparrow) + D(E_F^\downarrow)}$$

Poles of a Write Head

Structure in a write head that couples the magnetic fields to the write gap

Polycrystalline Solid

Polycrystalline material is not a single crystal as a whole, but composed of many small crystals randomly oriented in different directions. The small crystals in polycrystalline solids are called grains. These grains have irregular shapes and orientations. A polycrystalline material has grain boundaries where differently oriented crystals meet. Polycrystalline silicon is produced in the form of a ribbon or thin films

Polygonization

The motion of dislocations to form structures that resemble three-dimensional polygons. In this way, they minimize their strain energies. Readers are referred to the many excellent books on materials science that discuss dislocations and their interactions

Polymer Thick Films

are those that are cured at much lower temperatures than their cermet counterparts. The binding matrix is a polymer material and the resulting films can be used in flexible circuits

Positron Annihilation

Analytical technique that is sensitive to open defects, such as vacancies, in a crystal. The lifetime of positrons is greater when the total number of electrons is reduced, as happens at vacancies. Measuring positron lifetime can give semiquantitative estimates of the concentrations of these defects

Power Stabilizer

Optical device that can provide a fixed output intensity upon varying input intensity. The principle may be based on multi-photon absorption, which becomes efficient when light is more intense

Precursor

Volatile compound containing the element required for deposition onto the substrate

Process Integration

The carefully engineered combination of materials and processes to enable the fabrication of an integrated circuit technology. The careful consideration of materials properties, device physics and electrical engineering principles is required for successful integration of materials into an IC chip

Proper Ferroelectric

Ferroelectric material in which the spontaneous polarization is the primary order parameter

Pseudo-morphic Layers

True epitaxy only occurs when the lattice constants of the substrate (material A) and layer (material B) are equal. If they are different, misfit dislocations or even gross bending of the structure can occur. In pseudo-morphic growth, the lattice constants can be very different. However, before misfit dislocations can be formed, either the growth of B is stopped or a layer of the substrate material, A, is grown on top of the structure. In either case, the structure is stabilized with material B being severely strained. Manufacturers use this technique to produce devices with advanced electrical or optoelectronic properties

p-Type Conductivity

Semiconductor material in which the dopants create holes as the majority charge carrier. It is formed by doping with acceptor atoms

Pulse Width

Width of a pulse in a digital magnetic recording read head when sensing a recorded transition. Characterized by the 50% width (PW_{50})

Pyroelectric Effect

Generation of an electric polarization change or a charge separation in a material in response to a change in material temperature

Pyrolytic Boron Nitride (pBN)

This is the favored crucible material for GaAs growth from the melt and for Knudsen cells for MBE. Pyrolytic refers to its high-temperature capabilities

Q**Quantum Cascade (QC) Laser**

Light amplification by stimulated emission of radiation (laser) through inter-subband transitions and unipolar electron transport

Quantum Confined Stark Effect

The change in near-band-edge optical absorption in quantum wells that takes place when a high electric field is present

Quantum Dot (QD)

A semiconductor quantum heterostructure that is quantum confined in all three dimensions, for example

InAs islands embedded in a layer of GaAs and Ge islands in Si

Quantum Efficiency

Indicates either the probability that the absorption of a photon will result in the creation of a free electron and hole or the ratio of the number of luminescence photons to the number of stimulating photons. When determined by xerographic discharge of the photoreceptor QE is a measure of the overall effectiveness of surface charge neutralization per absorbed (or incident) photon. It is sometimes called xerographic gain or supply efficiency. When determined by spectroscopic methods, such as fluorescence quenching, it is a measure of charge generation within the light-absorbing moiety

Quantum Well (QW)

Low-dimensional semiconductor quantum heterostructure where a thin layer with lower bandgap is sandwiched between layers (barriers) with higher bandgap, leading to spatial confinement of carriers along one dimension for which the energy is quantized in discrete levels. Carriers have free motion in the plane perpendicular to the confinement direction. May be repeated to produce a multiple quantum well (MQW)

Quantum Well Inter-subband Photodetector (QWIP)

Long-wavelength (IR) detector based on light absorption through inter-subband electron transitions in n-doped QWs

Quantum Wire

Semiconductor quantum heterostructure with two-dimensional confinement of carrier motion.

Carriers have just one direction of free motion

Quantum-Confined Stark Effect (QCSE)

Response of the confined electrons and holes in a quantum well to a strong DC electric field applied in the growth direction

Quantum Size Effect

Quantum effect associated with quantization of the band and level. It is observed in two-, one- and zero-dimensional systems whose size becomes small

Quasi Particles

Unpaired electrons excited above the energy gap

Quasi-Fermi Levels

Levels that correspond to the energy positions the equilibrium Fermi level would need to have in the gap in order to produce equivalent carrier densities to the ones that are generated by the illumination

R

Radiation Resistance

This is important for solar cells operating in space where high doses of gamma rays and high energy particles can significantly degrade the efficiency of the cells

Radio-Frequency (RF) Circuits

High-speed and microwave analog circuits that operate in the range 0.1–100 GHz

Reactive Sputtering

Technique for preparing thin films by sputtering with gas mixture of reactive gas and conventional sputtering gas such as oxygen and argon

Reactor Cell

Chamber where the precursors react to deposit a film onto the substrate

Read Head

In magnetic recording the ferromagnetic device used to generate a voltage proportional to the state of magnetization in the recording medium

Reciprocal Lattice

Theoretical lattice constructed from a real lattice, such that any vector from the origin to a diffracted spot is normal to a particular plane in the real lattice, with reciprocal length of that plane spacing

Recombination

Process whereby non-equilibrium populations of electrons and holes return to their equilibrium values. Depending on whether the recombination rate is proportional to the excess carrier density or the square of that quantity, the processes can be referred to as linear and quadratic, or alternatively as monomolecular and bimolecular recombination. Radiative recombination refers to the transfer of at least some of the energy of the excess carriers into photons. Non-radiative recombination involves only the production by lattice phonons (heat)

Reflectometer

Instrument used for reflecting light off the substrate to monitor the growth process. This is normally achieved through detecting the interference modulation of the light intensity from a growing film

Reflow

Process of heating a glass above its glass-transition temperature, to the point that its viscosity is sufficiently reduced to enable the material to flow. In combination with surface tension effects or other external forces, reflow is often exploited in the reshaping of optical devices

Remanent Magnetization

is magnetization that remains in a sample after the magnetic fields are removed

Remanent Polarization

Dielectric polarization that remains in a ferroelectric material after an electric field has been applied

Resistivity

Parameter of a semiconductor that depends on the free electron and hole densities (cm^{-3}) and their respective mobilities (cm^2/Vs) and is expressed in units of $\Omega \text{ cm}$. It is the reciprocal of conductivity and it depends strongly on temperature in a semiconductor

Resolution

The smallest separation of two points in an object that can be distinctly reproduced within an image

Resonant Nonlinear Response

The nonlinear response taking place in the absorbing spectral region

Responsivity

Signal term often measured using a two-temperature black body. Units can be V/W (used for photoconductors) or V/photon (often used for multiplexed photodiodes)

Retrograde Solidus

Describes the shape of the solidus when it shrinks as the temperature is reduced. In GaAs, the increased width of the solidus at high temperatures indicates that concentrations of Ga or As, in excess of stoichiometry, can exist in the solid crystal. These concentrations must reduce as the crystal cools because of the retrograde solidus

RHEED

Glancing-angle electron diffraction technique, sensitive to surface reconstruction and morphology. Key in situ analytical technique in MBE

ROIC

Abbreviation for readout integrated circuit, commonly used to describe the silicon chip on which the detector material is mounted. The role of the ROIC is to integrate the signal, perform some signal processing and readout the array. Other terms are: multiplexer or mux

R-T Method

Defining the optical constants, based on two equations connecting the formers to the reflectance and transmittance of the slab sample of material under measurement

Rutherford Scattering

Elastic scattering of electrons due to an electrostatic interaction with the nucleus and surrounding electrons of an atom

S

Saturated Vapor Pressure (SVP)

Partial pressure of a substance in equilibrium with its liquid, so the partial pressure is determined solely by the temperature of the liquid and vapor

Saturation Intensity

Intensity at which the effective absorption decreases to a half of its initial value

Saturation Magnetization

Maximum magnetization that a ferromagnetic sample can attain in magnetic fields larger than the coercive field

Saturation of Absorption

Resonant nonlinear process in which absorption decreases with increased level of illumination

Scaling

Calculated reduction of integrated circuit element dimensions according to physical and engineering principles and constraints, as well as economic considerations (See *Moore's Law*)

Scanning Probe Microscopy

Generic term given to microscopy techniques that use a scanned micro- or nanoscale tip in immediate proximity to a surface to image topography or other physical features with almost atomic resolution. The main types are atomic force microscopy (AFM) and scanning tunneling microscopy (STM)

SCH Laser

Separate confinement heterojunction laser. In the SCH laser the optical and electrical confinements are achieved separately by altering the thickness and the alloy composition of the cladding layers

Schottky Contacts

Metal-semiconductor contacts are also named Schottky contacts

Schottky-Mott Rule

Schottky-Mott rule equates the barrier heights of n-type (p-type) Schottky contacts with the difference of the metal work function and the electron affinity (ionization energy) of the semiconductor. The rule is incorrect since it does not consider the *intrinsic* interface-induced gap states

Screen

Mask used to define the desired thick-film pattern. It is usually made of stainless steel, polyester or nylon

Screen Printing

Method by which thick films are deposited onto substrates. See also *antiferromagnetically coupled media* (AFM)

Secondary Electrons

Low-energy (< 50 eV) electrons that escape from the near sample surface, used to form topographic images

Secondary-Ion Mass Spectrometry (SIMS) and Glow Discharge Mass Spectrometry (GDMS)

Mass-spectrometric techniques that are well suited for the chemical analysis of semiconductors. In addition to being extremely sensitive to most impurities, they are quantitative and can give valuable information regarding the distributions of concentrations with depth. In SIMS, high-energy primary ions are focused on the sample surface. These sputter atoms from the material under investigation. Those that are charged are passed into a mass spectrometer for analysis. In GDMS, the sputtering is accomplished by a glow discharge. SIMS is, by convention, generally classified as dynamic, in that the material surface layers are continually removed as they are being measured, and static, in which the ion dose during measurement is restricted to less than 10^{16} ions/m² in order to retain the surface in an essentially undamaged state

Segregation Coefficient, k

In growth from the melt the incorporation of an impurity into the crystal depends on the equilibrium ratio of the solubilities in the melt and the solid. For a dilute solution, this ratio is given by the ratio of the equilibrium value of impurity concentration at the solidus and the liquidus at the growth temperature. This ratio is the segregation coefficient, k . For most impurities, k is less than unity and the growing crystal contains a lower impurity concentration than in the source melt. The exploitation of this fact has resulted in the purification technique of *zone refining*

Selection Rule

Quantum-mechanical rule based on wave-function and operator symmetry that determines oscillator strength; typically set by parity or angular-momentum considerations

Selective Epitaxy

Growth of a single-crystal layer in a window without any deposition on the surrounding mask layer

Selenization

Process of forming the CIGS or CIS layer by exposing a copper, indium and gallium precursor layer to Se to form the alloy

Self-Assembly

Spontaneous formation of a layer of organic material on a solid substrate surface. The process usually takes place by immersing the substrate into a solution of the organic compound. The driving force for the self-assembly can be chemical and/or electrostatic attraction

Self-Defocusing

A nonlinear process associated with negative refractive nonlinearity that results in spatial spreading of intense light

Self-Focusing

A nonlinear process associated with positive refractive nonlinearity that results in focusing of intense light

Semi-Insulating

This is a term given to semiconductors whose resistivity lies above about $10^6 \Omega \text{ cm}$. In GaAs, semi-insulating properties normally lie in the range of $10^7 - 10^8 \Omega \text{ cm}$

Semiconductor Detector

Device that converts the incident photons directly into electrical pulse

Semiconductor Nanocrystals

Composite materials made out of semiconductor quantum dots embedded in organic or glass hosts

Shallow-Energy-Level Dopant

Doping impurities whose energy level lies very close to the conduction or valence band for donors or acceptors

Shear Modulus

Sometimes also called the rigidity, relates stress and strain according to Hooke's law and is a measure of

a material's resistance to shearing stress. The shear modulus therefore has units of pressure

Sheet Resistance

Resistivity of a semiconductor sample divided by its thickness, measured in Ω / square . It is commonly used by integrated circuit designers when designing resistances by specifying the number of required squares required to give a certain value of resistance

Shields

Soft ferromagnetic films used to direct the flux from a recording layer away from sensor films in a read head

Short-Range Atomic Structure

Atomic bonding structures within a scale of $\approx 0.5 \text{ nm}$, which are characterized by coordination number (the number of nearest-neighbor atoms), bond length, and bond angle. It is demonstrated for such simple glasses as SiO_2 that the short-range structure is nearly the same with that in a corresponding crystal

Signal Decay Rate

Rate (R) at which the amplitude of a signal read back from a recording system decays with time

$$R = 100 \frac{\frac{A(t)}{A(t_0)} - 1}{\log(t/t_0)}$$

Single-Layer Organic Photoconductor

A photoconductor with an architecture where the charge-generation and charge-transport functions are combined into a single layer

Slider

In a disk drive, the structure used to support on an air bearing the write and read heads over the recording medium

Sliding Boat

Liquid-phase epitaxy technique in which the substrate is slid under the melt in a horizontal orientation

Slope Parameter

(In perpendicular magnetic recording) The slope of the magnetization curve at the coercive field times

$$4\pi\alpha = 4\pi \frac{dM}{dH(H=-H_c)}$$

Slush

Homogeneous charge of a ternary is held across the liquidus–solidus gap with the lower end solid, the upper end liquid and the central section in a slushy state, during recrystallization

Smectic Phase

Liquid-crystal phase with some long-range translational order in addition to the long-range orientational order of a nematic. The constituent rod-like molecules are arranged in layers giving translational order in one dimension

Soft Underlayer (SUL)

Magnetically soft (low-coercivity) film underneath the recording layer in a perpendicular magnetic recording system. Used as a low-reluctance path for the flux from the write head

Solar Cell

Semiconductor device that converts the energy of sunlight into electric energy. Also called photovoltaic cell

Solid/Liquid/Gaseous Phase Equilibria

These phase equilibria are essential for understanding both the various growth techniques used and in understanding post-growth heat treatments, i.e. cool-down after growth and subsequent annealing stages

Solidus

In an equilibrium phase diagram, the solidus is the line below which all the components are solid

Solitonic Propagation Of Pulses

Propagation of pulses characterized by a lack of temporal pulse spreading

Spatial Frequency

Spatial frequency is the reciprocal of a spatial dimension (e.g., height x or width y in two-dimensional image) similar to the temporal frequency, which is the reciprocal of time. However, the unit of spatial frequency is preferably expressed as line pairs/mm (lp/mm), instead of cycles/mm

Specific Heat

(also called the specific heat capacity). Amount of heat required to change a unit mass (or unit quantity, such as mole) of a substance by one degree in temperature

Spherical Aberration

A blurring of resolution due to the spread of path lengths of rays traveling from an object to the image plane, arising from a variation of the focal length of a lens as a function of distance from the center of the lens

Spin Valve

Read head that uses the giant-magnetoresistive effect in three metallic films: the ferromagnetic free film, a non-magnetic spacer film and a ferromagnetic pinned film

Spontaneous Polarization

The electric polarization that a substance possesses in the absence of an external electric field

SPRITE

Abbreviation for signal processing in the element: a device used in the UK common module camera. It relies on a strip of CMT with a high voltage bias to drift photon generated holes at the same speed as the image is scanned, so resulting in an amplified signal at the end of the strip

Sputter Depth Profile

Compositional depth profile obtained when the surface composition is measured as material is removed by sputtering. Note: in some analytical methods such as SIMS, the sputtering is often accomplished by the ion beam used for analysis, but in other methods an ion beam may need to be added

Sputtering

Process in which atoms and ions are ejected from the sample as a result of particle bombardment

Squeegee

Device used to transfer the thick-film paste through a screen and onto the substrate

SRAM

Static random-access memory

SSR

Solid-state recrystallization is a growth technique that produces a homogeneous but polycrystalline charge that is subsequently recrystallized in the solid state to produce multi-grained material

Stepanov Technique

Crystals are pulled from a crucible containing a crystal-shaped aperture

Stoichiometry

State of a perfect compound where the ratio of the numbers of atoms of the elements is a simple fraction. In GaAs, for example, stoichiometry exists when the number of As and Ga atoms are equal

Stokes Shift

Difference in energy between the maximum of the emission spectrum and the maximum of the excitation spectrum

Strain (ϵ)

Defined in elementary form as the change in length divided by the original length., it can be thought of as the movement of one corner of a cubic box from its initial position under stress

Strained Quantum Well

QW layer grown on a substrate with a different lattice constant, resulting in a significant strain of the QW layer lattice

Stress

Force per unit area provided either by gravity or by the flow of viscous fluid

Strong Anchoring

Strong anchoring of the director at a surface parallel to the easy axis is said to occur when an applied field is unable to alter the orientation of the director at the surface but can in the bulk

Structural Relaxation

Essentially an aging effect associated with glasses. Because glasses are metastable materials with random network structures, they are inherently subject to short- or long-term changes in material properties. Often, structural relaxation is manifested by a change in specific volume (densification) at fixed temperature versus time. The rate of such changes is extremely sensitive to the difference between the glass transition temperature and the observation temperature. Structural relaxation can be induced rapidly by an annealing step, in which the glass is heated near its glass-transition temperature for some period of time

Substitutional Impurities

Impurities that replace the crystal's base atom at that base atom's lattice position

Substrate

Base material onto which a film is deposited.

Examples of typical substrates include materials such as alumina, beryllia, aluminum nitride, silicon, insulated steels and various plastics. In epitaxial processes, substrates are normally near lattice-matched pieces of material of a sufficiently large area for use in the various epitaxial growth processes, normally from similar, i. e. common-cation, ternary systems, e.g. CdZnTe for CMT

Superconductors of Type I

Characterized by the fact that normal and superconducting regions cannot coexist in these materials. The value of $\kappa = \lambda_L/\xi$ is smaller than $1/\sqrt{2}$

Superconductors of Type II

Type II superconductors, for which $\kappa = \lambda_L/\xi > 1/\sqrt{2}$, show perfect diamagnetism only below the lower critical field B_{c1} . Between the lower and the upper critical fields type II superconductors are in the mixed state. Magnetic flux enters the superconductor via the normal conducting cores of the flux lines

Supercooling Temperature

Difference between the glass-transition temperature and the in-use temperature for a glass-based device. For a large (small) supercooling temperature, the structural relaxation rate is low (high)

Superlattice (SL)

Structure of repeated QWs with thin barriers allowing the coupling of wave-functions from adjacent QWs and the subsequent delocalization of the energy levels

Superlattice Avalanche Photodiode (SL-APD)

Avalanche photodiode architecture where an SL is incorporated in the carrier multiplication region for the purpose of reducing the dark current as well as the excess noise factor

Superparamagnetism

In small ferromagnetic particles the magnetization can flip from one state to the opposite state under thermal excitation. This behavior is similar to a paramagnet. The resistance of the particle to switching is characterized by a thermal stability factor $= \frac{K_u V}{k_B T}$, where K_u is the uniaxial anisotropy factor for the particle, V is the particle volume, k_B is the Boltzmann constant, and T is the absolute temperature

Supersaturation

Ratio between the species concentration and its solubility limit/equilibrium concentration at a given temperature when this ratio is larger than 1

Superstrate

Describes the thin-film configuration where the glass substrate acts as the window for solar radiation and therefore needs a TCO layer before the photovoltaic structure can be deposited

Surface-Mount Devices (SMDs)

Electronic components that are attached to the surface of a circuit board as opposed to having through-hole connections. They are a characteristic feature of a hybrid circuit

Surface Passivation

Semiconductor surfaces are often electrically active and appear to be covered with a high density of deep-level states. These can greatly affect the properties of a device. Fortunately, it is often possible to treat the surface to substantially reduce this density to values that do not affect device operation. This is surface passivation. In GaAs, passivation is often accomplished by covering the surface with a layer of GaAlAs. Also, see passivation

Susceptor

This is normally made of high-density graphite and is used to transfer the heat from the heater (possibly RF coupling straight into the susceptor) to the substrate

SW

Abbreviation for short wave, often used for wavelengths between $1.0\ \mu\text{m}$ and $3\ \mu\text{m}$. The atmosphere is transparent in relatively narrow bands within the SW region, the most common one is between 2.0 and $2.25\ \mu\text{m}$, although $1.5\ \mu\text{m}$ is also important as this is the wavelength for eye-safe lasers

Synthetic Antiferromagnet

Sequence of films: antiferromagnet/ferromagnet/ruthenium/ferromagnet. An example is: MnFe/Co/Ru/Co. With a thin Ru film, the final ferromagnetic film is antiferromagnetically coupled to the first ferromagnetic film. The coupling between the two ferromagnetic films is characterized by the exchange coupling parameter J_{12} (erg/cm^3 or J/m^3)

Synthetic Ferrimagnetic Media (SFM)

Magnetic recording media in which there are two ferromagnetic layers of unequal thickness coupled by a thin layer of ruthenium (Ru), sometimes referred to as "Pixie Dust". The two layers are antiferromagnetically coupled. The coupling between the ferromagnetic films is characterized in terms of the antiferromagnetic coupling between the thinner layer (layer 2) and Ru and the media flux from that layer by an exchange magnetic field $H_{\text{ex}} = J_{\text{ex},2}/M_2 t_2$

T**T Nonlinear Figure of Merit**

Figure of merit that describes the applicability of a refractive nonlinear optical material in terms of the Kerr coefficient and two-photon absorption

Tail States

Localized states in the tail of band, i. e. conduction band and valence band, which generally have an exponential density-of-states function

Tauc Gap

Tauc discovered that, in many chalcogenide glasses such as As_2S_3 , optical absorption spectra α around the fundamental edge can be fitted as $\alpha\hbar\omega \propto (\hbar\omega - E_g)^2$, where E_g is called the Tauc gap. The energy is often used as a measure of optical bandgap, while its theoretical interpretation is not conclusive

Technology Node

Minimum half-pitch of metal interconnect is most representative of the process capability enabling high-density (low cost/function) integrated circuits and is selected to define an ITRS technology node. For each node, this defining metal half-pitch is taken from whatever product has the minimum value. Historically, DRAMs have had leadership on metal pitch, but this could potentially shift to another product in the future. Other parameters are also important for characterizing IC technology. For example, in the case of microprocessors (MPUs), physical bottom gate length is most representative of the leading-edge technology level required for maximum performance. Each technology node step represents the creation of significant technology progress in metal half-pitch – approximately 70% of the preceding node, 50% of two preceding nodes. (From [IRTS 2003])

Temperature Coefficient of Resistance (TCR)

Denotes the sensitivity of a resistor material to changes in temperature. It is usual to quote TCR in terms of parts per million (ppm) per $^{\circ}\text{C}$

Tensile Strain

Type of strain obtained when a strained Si layer is grown on a relaxed $\text{Si}_{1-x}\text{Ge}_x$ layer

Ternary and Quaternary Alloys

These are alloys containing three or four components, respectively. GaAlAs and GaAlAsP are examples

Thermal Budget

Term describing the temperature–time product associated with an IC annealing process step. Material stability and morphology is typically very sensitive to annealing temperature for a period of time

Thermal Conductivity

(heat conductivity) Heat flow across a surface per unit area per unit time, divided by the negative of the rate of change of temperature with distance in a direction perpendicular to the surface

Thermal Expansion Coefficient

Fractional change in length or volume of a material for a unit change in temperature

Thermal Nonlinearities

Nonlinear effect associated with heating of the materials by intense light

Thermally Stimulated Current (TSC) spectroscopy

TSC is a useful technique for assessing concentrations of deep levels in high-resistivity semiconductors. These levels are filled optically with light above the bandgap energy. They are emptied sequentially, with

the sample under bias, as the sample temperature is raised. Defects of different ionization energies produce separate peaks in the graph of current as a function of temperature

Thermistors

Thermally sensitive resistors that exhibit a change in resistance when the temperature is altered. The most common forms have a negative TCR, meaning that the resistance decreases as the temperature increases

Thermomechanical Fatigue

Occurs when materials with different CTE are joined and used in an environment that experiences cyclic temperature fluctuations resulting in imposed cyclic strain that results in damage to the joined materials

Thermophotovoltaic (TPV)

Absorption of solar radiation and re-emission of infrared radiation that is then converted into electricity by absorption in a narrow-bandgap cell

Thermotropic

Liquid crystals are those where the transition from one phase to another occurs on changing the temperature

Thick Film

Layer deposited onto a substrate by the process of screen printing

Threading Dislocations

This term is applied to dislocations that are formed at an interface and that *thread* their way into the epitaxial layer

Threshold Voltage (V_{th})

Voltage at which an inversion layer forms in the semiconductor substrate of an MIS structure. For applied voltages beyond this threshold, the transistor turns on, i. e. a conducting channel is established between the transistor source and drain, as observed by the increase in drive current

Time Division Multiplexing

Multiplexing technique used in modern optical networks that allows close spacing in time of bits in a single channel

Time-Domain Charge Measurement (TDCM)

TDCM is a rapid technique for the non-contacting measurement of electrical resistivity in SI materials. Its speed and high spatial resolution allows TDCM to be used in a mapping system

Tipping

Liquid-phase epitaxy technique in which the melt is moved over the substrate in a tipping furnace

Transferred Electron Effect

This is a somewhat unusual effect where conduction-band electrons can exist in alternative conduction-band states. In GaAs, the lowest conduction-band minimum corresponds to zero electron momentum. The application of an electric field can excite electrons into subsidiary minima of somewhat greater energy from where they will relax back to their original states. If the effective mass of the

electrons in the subsidiary minima is greater than that in the primary minimum, negative differential resistance can be realized. This effect can be found in GaAs, InP and certain alloys

Transistor

A three-terminal device in which the current flow between two terminals (called the source and drain regions) is controlled by the voltage applied between a third terminal (the gate electrode) and one of the two terminals

Transit Time

Refers to the difference in time between the moment a charge carrier is generated at one end of the sample and its arrival at the other end. It is the primary result in time-of-flight experiments. In xerography, transit time is the time for a photoinjected carrier to traverse the charge-transfer layer

Transparent Conducting Oxide (TCO)

Thin layer of highly conducting material that is used as the front contact in thin-film solar cells. The requirement of high optical transmission over a wide spectral range is important to allow as much of the sunlight through to the absorber layer

Transverse Magnetic Bias Film

In a magnetoresistive head, an antiferromagnetic film coupled to the pinned film to maintain the magnetization of the pinned film in a direction transverse to the magnetization of the recording film

Trapping Centers

Irregular sites in the photoconductor with localized electronic energy levels inside the bandgap. Such sites will trap charge carriers and thus inhibit electrical conduction

Traveling Heater Method

A molten zone is made to migrate through a homogeneous solid source material

Trimming

Process by which the value of thick-film elements can be adjusted. Usually achieved by using a laser or air abrasive jet

Tunneling Magnetoresistance (TMR)

With two ferromagnetic films coupled by a thin insulating layer, electrons can tunnel through the insulating layer and the magnetoresistance coefficient is given in terms of the polarization ratio for the two contacts as $\frac{\Delta R}{R} = \frac{2P_1 P_2}{1 - P_1 P_2}$.

Tunneling Conduction

Process for charge conduction where the charge carriers pass through an energy barrier by quantum-mechanical tunneling

Twin Crystal

Crystal having two or more crystals or crystal sections that, when regularly positioned, are in reverse position relative to the other sections

Two-Photon Absorption

Nonlinear process in which a simultaneous absorption of two photons results in an electronic transition

U

UHV

Ultra-high vacuum is a vacuum better than 10^{-9} Torr

Ultrafast Nonlinear Response

Nonlinear response taking place in the non-absorbing spectral region

Underfill

Dielectric composite organic material that is bonded between the chip and substrate of a flip-chip device to help mechanically interlock the chip to the substrate. The underfill material is typically a silica-filled anhydride resin polymer

Uniaxial Anisotropy

Magnetic anisotropy along one direction in a ferromagnetic material and characterized by a uniaxial anisotropy parameter K_u (erg/cm³ or J/m³)

Uniform Planar Alignment

of the director is when the director is parallel to the surface and to a particular direction in the surface. This has also been referred to as homogeneous alignment

Unipolar Avalanche Photodiode (UAPD)

QWIP detector employing avalanche multiplication of only one type of carrier via intra-QW impact ionization by carrier-carrier scattering

Upper Critical Field (B_{c2})

The highest magnetic field allowing the existence of the superconducting mixed state in the type II superconductor considered

V

V/I boundary

Denotes the spatial location of the transition from the vacancy-dominated region to the Si interstitial dominated region and vice versa

Vacancy

Regular lattice site from which the host atom is missing. Anion (cation) vacancies are generally donors (acceptors)

Valence Band

Highest range or band of energies in a semiconductor where electrons are normally present at zero temperature. When electrons are promoted from this band, holes are left behind that contribute to the electrical conductivity

Vapor Growth Techniques

Growth takes place via a vapor phase: particularly useful for high-melting-point materials, or those with high partial pressures of one constituent, e.g. ZnS

Vapor-Phase Epitaxy (VPE)

This is a form of epitaxy where the components of the layer to be grown are transported to the substrate as a vapor. Decomposition of these components to produce the layer occurs because the substrate is heated, often on a support called a susceptor. The different types of VPE are discussed in the text

(VCSEL)

Vertical-cavity surface-emitting laser. One of the more modern forms of semiconductor laser, employing the high gain of quantum wells in a low-loss optical cavity

Vegard's Law

States that the lattice parameter of an alloy material is given by the concentration weighted average of the constituents

Vehicle

Liquid component of the thick-film paste. Typically contains a resin dissolved in a solvent. It is removed during the drying and firing processes

Verneuil Technique

Rapid growth method used for many high-melting-point materials, mainly oxides

Vertical-Gradient Freeze Technique

Similar to Bridgman but freezing is controlled by moving a temperature gradient along a stationary crucible

Vertical Transport

Mechanisms of carrier transport parallel to the growth direction in a semiconductor quantum-confined structure

Vertical-Cavity Surface-Emitting Laser (VCSEL)

QW diode laser emitting through its top semiconductor surface

VI Recombination

Mutual annihilation between vacancies and Si interstitials

Virtual Gap States

The virtual gap states are the *solutions* of Schrödinger's equation for complex wave vectors in the energy gap. The continuum of these *virtual* states is the source of *real* impurity states in the bulk as well as of surface states and the interface-induced gap states at *real* surfaces and interfaces, respectively, provided the corresponding boundary conditions are considered

Void

see COP

VPE

A general term used to describe the deposition of an epitaxial thin film from the vapor phase

W**W Nonlinear Figure of Merit**

Figure of merit that describes the applicability of a refractive nonlinear optical material in terms of nonlinear index change and linear absorption

Wavelength Division Multiplexing

Multiplexing technique used in modern optical networks that involves sending many signals in parallel at closely spaced wavelengths along the same fiber

Weak Links

Large-angle grain boundaries in cuprate superconductors, which act as barriers for the supercurrents

Web Photoreceptors

Devices where the layers are coated on an insulating polymeric support and subsequently fashioned into a loop

Wire Bonding

Process where a thin wire (can be less than 25 μm) made of Au or Al is bonded to the surface of an integrated circuit and then to a pad or a leadframe in the package

Work Function

The energy (usually measured in electron volts) needed to remove an electron from the Fermi level in a solid to outside the surface

Write Efficiency

Ratio of the magnetic field times write gap to the magnetomotive force (turns times current) in the write coil

Write Gap

Region in a write head that generates the magnetic fields that couple to the recording medium. Characterized by the gap length g

Write Head

In magnetic recording the ferromagnetic device used to generate magnetic fields from current that can switch the state of the magnetization in the recording medium. In disk drives the ferromagnetic device is made using thin films

Wrong Bond

Homo-polar bonds in stoichiometric glasses, such as As–As in As_2S_3 . The defective bond nominally does not exist in the corresponding crystal. However, specifically in covalent glasses such as As_2S_3 , the bond exists with a concentration of $\approx 1\%$, which depends upon preparation methods and so forth

Würtzite Structure

Comprises two interpenetrating close-packed hexagonal lattices, one for cations and the other for anions. Each anion (cation) has four cation (anion) nearest neighbors. In principle diffusion should be anisotropic but meagre available evidence indicates only slight effects

X**Xerographic Discharge**

Time-dependent decrease in surface potential with exposure of a charged OPC

Xerographic Gain

or quantum efficiency of supply is the fractional number of surface charges neutralized per absorbed photon

Xerography

Name coined by Chester Carlson for electrophotography using dry powder marking particles

X-Ray

Form of energetic electromagnetic radiation of wavelength ≈ 0.1 nm

X-Ray Diffraction

A highly sensitive technique for measuring the lattice constant of crystalline solids, see B K Tanner and D. K Bowen, 1980

X-Ray Photoelectron Spectroscopy (XPS)

Method in which an electron spectrometer is used to measure the energy distribution of photoelectrons and Auger electrons emitted from a surface irradiated by X-ray photons

X-Ray Sensitivity

The X-ray sensitivity of a photoconductive detector is the collected charge per unit area per unit exposure of radiation

X-Ray Topography

This is a method for sampling the diffraction condition of X-rays from a surface in order to observe changes in lattice constant. The X-rays are scanned over the surface and an image is built up from changes in the

fraction diffracted at a particular angle. Changes in lattice constant resulting from strain or changes in composition can be imaged in this way

Y**Yield Strength**

Applied stress (in pounds per square inch or psi in the English system, megapascals or MPa in the metric system) under which an object experiences plastic deformation

Young's Modulus

Ratio of a simple tension stress applied to a material to the resulting strain parallel to the tension. Therefore Young's modulus has units of pressure

Z**Zinc-Blende Structure**

A crystal structure that has two interpenetrating face-centered cubic lattices, one for the cations and the other for anions. Each anion (cation) has four anion (cation) nearest neighbors. Diffusion is isotropic

Zone Refining

Technique used to repeatedly pass zones of molten material through a solid bar in order to purify it, either for use directly in applications or to produce pure starting materials, e.g. elements for compound semiconductors

 vacancy 1363
 – aggregation 109
 – concentration 110, 115, 123, 125
 – diffusivity 112
 – flux 124
 – formation energy 104
 vacuum deposition 663
 vacuum distillation 838
 vacuum field effect transistor (VFET)
 – diamond 554
 vacuum permittivity 48
 valence band 1363
 valence band (VB) 57, 890, 1221
 – amorphous semiconductors 566

 – deformation potentials 747
 – offset 152
 valence band offset 154, 157
 valence electrons 60
 valence-alternation pairs (VAP) 567
 van der Pauw technique 413
 van Hove singularities 59
 vapor growth 246
 vapor growth techniques 1363
 vapor pressure controlled Czochralski (VCZ) 244
 vapor sensing 1254
 vapor-phase epitaxy (VPE) 6, 325, 508, 873, 889, 1364
 variable-range hopping (VRH) 172, 705, 1113
 (VCSEL) 1364
 vector flow epitaxy (VFE) 285
 Vegard's law 1364
 vehicle 1364
 velocity–field characteristic 811
 – AlN 813
 – GaN 813
 – Group III–V nitride semiconductor 813
 – InN 813
 Verdet constant 69
 Verneuil growth method 233, 237, 250
 Verneuil technique 1364
 vertical dipper LPE 876
 vertical gradient freeze (VGF) 237, 245, 506
 – GaAs 506
 vertical transport 1030, 1364
 vertical unseeded vapor growth (VUVG) 246
 vertical-cavity surface-emitting laser (VCSEL) 531, 889, 1021, 1032, 1364
 – active region 905
 – beam profile 905
 – semiconductor–air interface 905
 vertical-gradient freeze technique 1364
 VI recombination 1364
 via-hole device 875
 – Group (I–V) characteristics 869
 vibration dynamics 207
 vibrational mean energy 386
 virtual gap states 1364
 virtual gap states (ViGS) 153
 viscosity coefficient
 – Miesowicz experiments 930
 – nematodynamics 931
 viscous torque 931

void 1364
 – density 111
 – size 107
 Volmer–Weber (VW) growth 332
 voltage noise measurement 432, 433
 – low-impedance devices 433
 voltage scaling 629
 vortex structures 1187
 VPE 1364
 VPE growth
 – group II–VI wide bandgap 330
 – source materials 330

W

W nonlinear figure of merit 1364
 wafer fusion 1008
 Wannier–Mott excitons 63
 waste in electrical and electronic equipment (WEEE) 1277
 wave
 – in-plane 1027
 wave function
 – Bloch-type 442
 wave soldering 727
 wavelength dispersive X-ray analysis (WDX) 343
 wavelength division multiplexing 1364
 weak absorption tail (WAT) 62
 weak links 1364
 web photoreceptors 1364
 white-light LED 13, 992
 wide bandgap
 – compounds 325, 332
 – electron mobilities 774
 – epitaxial growth 328
 – Group II–VI compound semiconductors 327
 – Group II–VI compounds 328
 – InN 774
 – materials 781
 – quantum dot 332
 – quantum well 332
 – semiconductor 147, 158, 537, 538
 wide-band X-ray 839
 Wiedemann–Franz–Lorenz law 395
 windows growth 235
 wire bonding 726, 1364
 – digital applications 1272
 – materials 1272
 work function 700, 1030, 1364
 write efficiency 1364
 write gap 1364

write head 1364
 – efficiency 1161
 write pole tip 1180
 wrong bond 1364
 wurtzite
 – AlN 809
 – GaN 761, 811
 – Group III–V binaries 747, 748
 – Group III–V semiconductors 747
 – structures 755
 Würtzite structure 1364
 WZ-GaN
 – specific heat 765

X

xerographic discharge 965, 1364
 xerographic gain 1365
 xerography 955, 1365
 XeroX Copier 955
 X-ray 11, 1365
 X-ray absorption fine-structure (XAFS) spectroscopy 1141
 X-ray absorption near-edge structure (XANES) 1141
 X-ray absorption spectroscopy (XAS) 758
 X-ray damage 1124
 X-ray diffraction 1365
 X-ray diffraction (XRD) 331, 354, 523, 1141
 – crystal plane spacings 350
 X-ray emission 344
 X-ray fatigue 1124

X-ray image
 – clinical 1130
 – detector 1123
 – photoconductor 1130
 – sensors 1124
 X-ray lithography 1007
 X-ray photoconductor 1122, 1123
 – absorbed energy 1131
 – material properties 1131
 – properties 1123
 X-ray photoelectron spectrometry (XPS) 343
 X-ray photoelectron spectroscopy (XPS) 373, 636, 1365
 – primary excitation 375
 X-ray sensitivity 1365
 X-ray storage 983
 – phosphor (XRSP) 993
 X-ray topography 1365
 X-ray-sensitive electron-beam image tube (XEBIT) 1130

Y

YAG (yttrium aluminium garnet) 726
 yellow luminescence 785
 yield strength 1365
 Young's modulus 757, 1365
 – semiconductors 740
 yttrium stabilized zirconia (YSZ) 547
 Y-type construction 1246
 Y-type deposition 1231

Z

ZBLAN glass 389
 Zeeman energy 81, 88
 zero-phonon transition 988
 zinc compound 684
 zinc selenide (ZnSe) 12
 zincblende structure 500, 755, 1365
 zirconia auto exhaust sensor 223
 zirconia based systems 225
 Zn in GaAs
 – diffusion profiles 512
 ZnBeSe
 – Be content 848
 ZnO
 – deep green luminescence 849
 – MBE-grown 850
 – optical properties 850
 – p-type doping 849
 – quantum wires 851
 – single crystals 336
 – undoped 850
 – wide band gap 843
 ZnSe 849
 – delta-doping 843
 – DX centers 843
 – epitaxial layer 330
 – N doping 843
 – p-type doping 843
 – single crystal 338
 ZnSe-based devices 843
 zone refining 1365
 zone-refining 5
